PAPERS AND PROCEEDINGS

(In May 1966 Number)

ALLOCATION AND DISTRIBUTION THEORY: TECHNOLOGICAL INNOVATION AND PROGRESS

Change and Innovation in the Technology of Consumption.....	K. J. LANCASTER.....	14
Profit Maximization, Utility Maximization, and the Rate and Direction of Innovation.....	W. FELLNER.....	24
The Role of Technological Innovation in Theories of Income Distribution.....	B. A. CORRY.....	33
<i>Discussion</i> by H. BREMS, J. S. CHIPMAN, T. SCITOVSKY.....		43

ANTITRUST AND PATENT LAWS: EFFECTS ON INNOVATION

Anniversaries of the Patent and Sherman Acts: Competitive Policies and Limited Monopolies...	M. S. MASSEL.....	284
The Joint Effect of Antitrust and Patent Laws upon Innovation.....	J. W. MARKHAM.....	291
Patents, Potential Competition, and Technical Progress.....	A. PHILLIPS.....	301
<i>Discussion</i> by C. D. EDWARDS, A. E. KAHN, R. B. HEFLEBOWER.....		311

CAPITAL THEORY: TECHNICAL PROGRESS AND CAPITAL STRUCTURE

Sources of Measured Productivity Change: Capital Input.....	Z. GRILICHES AND D. W. JORGENSEN.....	50
Toward a Theory of Inventive Activity and Capital Accumulation.....	K. SHELL.....	62
Investments in Humans, Technological Diffusion, and Economic Growth.....	R. R. NELSON AND E. S. PHELPS.....	69
<i>Discussion</i> by E. F. DENISON, K. SATO, J. HIRSCHLEIFER.....		76

ECONOMIC DEVELOPMENT: ADVANCED TECHNOLOGY FOR POOR COUNTRIES

Transport Technologies for Developing Countries.....	J. R. MEYER.....	83
The Capacity to Assimilate an Advanced Technology.....	R. SOLO.....	91
Notes on Invention and Innovation in Less Developed Countries.....	R. S. ECKAUS.....	98
<i>Discussion</i> by B. A. DE VRIES, L. G. REYNOLDS, W. F. STOLPER.....		110

ECONOMIC KNOWLEDGE, THE PRODUCTION AND USE OF

Economic Research Sponsored by Private Foundations.....	R. L. NELSON.....	519
The Production and Use of Economic Knowledge.....	R. D. CALKINS.....	530
Trends, Cycles, and Fads in Economic Writing.....	M. BRONFENBRENNER.....	538
<i>Discussion</i> by H. H. Villard, J. L. Mosak.....		553

THE ECONOMICS OF BROADCASTING AND ADVERTISING

The Economics of Broadcasting and Government Policy.....	R. H. COASE.....	440
The Quest for Quantity and Diversity in Television Programming.....	D. M. BLANK.....	448
Supply and Demand for Advertising Messages.....	L. G. TELSER.....	457
<i>Discussion</i> by H. J. BARNETT, H. H. GOLDIN, P. O. STEINER.....		467

THE ECONOMICS OF EDUCATION

Education and the Distribution of Earnings.....	G. S. BECKER AND B. R. CHISWICK.....	358
---	--------------------------------------	-----

Investment in the Education of the Poor: A Pessimistic Report.....	E. SMOLENSKY.....	370
Measurement of the Quality of Schooling.....	F. WELCH.....	379
Discussion by L. R. MARTIN, A. M. RIVLIN, A. DANIERE.....		393
THE ECONOMICS OF PUBLISHING		
The Market for Professional Writing in Economics.....	A. J. MORIN.....	401
The Pricing of Textbooks and the Remuneration of Authors.....	P. M. HORVITZ.....	412
The Economic Rationale of Copyright.....	R. M. SCHUCHMAN.....	421
Discussion by R. E. SLESINGER, R. W. FRASE, A. A. ALCHIAN.....		433
THE ECONOMICS OF SCIENCE POLICY		
National Science Policy: Issues and Problems.....	E. MANSFIELD.....	476
Science Policy and National Defense.....	A. YARMOLINSKY.....	489
Some Aspects of the Allocation of Scientific Effort between Teaching and Research.....	M. D. INTRILIGATOR AND B. L. R. SMITH.....	494
Discussion by W. CAPRON, M. J. PECK, E. G. FUBINI.....		508
ELY, RICHARD T., LECTURE		
The Economics of Knowledge and the Knowledge of Economics.....	K. E. BOULDING.....	1
INTERNATIONAL ECONOMICS: PROGRESS AND TRANSFER OF TECHNICAL KNOWLEDGE		
Labor Skills and Comparative Advantage.....	D. B. KEESING.....	249
Transfer of Technical Knowledge by International Corporations to Developing Economies.....	J. BARANSON.....	259
The International Flow of Human Capital.....	H. B. GRUBEL AND A. D. SCOTT.....	268
Discussion by S. HYMER, B. A. WEISBROD, H. G. JOHNSON.....		275
LABOR ECONOMICS: EFFECTS OF MORE KNOWLEDGE		
Information Networks in Labor Markets.....	A. REES.....	559
Educational Attainment and Labor Force Participation.....	W. G. BOWEN AND T. A. FINEGAN.....	567
Skill, Earnings, and the Growth of Wage Supplements.....	R. G. RICE.....	583
Discussion by W. L. HANSEN, R. EVANS, JR., J. SHISTER.....		594
MONEY AND BANKING: INNOVATIONS IN FINANCE		
Effects of Automation on the Structure and Function of Banking.....	G. W. MITCHELL.....	159
Recent Innovations in the Functions of Banks.....	A. J. MEIGS.....	167
Innovations in Interest Rate Policy.....	F. MODIGLIANI AND R. SUTCH.....	178
Discussion by W. I. SMITH, A. R. KOCH, B. G. MALKIEL.....		198
PUBLIC FINANCE: PROMOTION OF KNOWLEDGE PRODUCTION AND INNOVATION		
Tax Treatment of Individual Expenditures for Education and Research.....	R. B. GOODE.....	208
The Tax Treatment of Research and Innovative Investment.....	R. E. SLITOR.....	217
The Efficient Achievement of Rapid Technological Progress: A Major New Problem in Public Finance.....	R. K. NELSON.....	232
Discussion by D. H. ELDRIDGE, M. J. BAILEY, W. C. STUBBLEBINE.....		242

PUBLIC REGULATION: THE IMPACT OF CHANGING TECHNOLOGY

Community Antenna Television Systems and the Regulation of Television Broadcasting.....	F. M. FISHER.....	320
Regulation and Technological Destiny: The National Power Survey.....	W. R. HUGHES.....	330
New Technology and the Old Regulation in Radio Spectrum Management.....	H. J. LEVIN.....	339
<i>Discussion</i> by B. W. LEWIS, G. W. WILSON, W. IULO.....		350

THE SOVIET ECONOMY, KNOWLEDGE, INFORMATION AND INNOVATION IN

Innovation and Information in the Soviet Economy..	G. GROSSMAN.....	118
Libermanism, Computopia, and Visible Hand: The Question of Informational Efficiency.....	F. NEUBERGER.....	131
The Environment for Technological Change in Soviet Agriculture.....	D. G. JOHNSON.....	145
<i>Discussion</i> by A. ECKSTEIN, J. S. BERLINER		154

CONTRIBUTORS:

Leading articles are marked (a); communications (c); papers read at the annual meeting published in the Papers and Proceedings, separately paged, are marked (p); and all others are book reviews.

THE ECONOMIST AND THE POPULATION QUESTION*

By JOSEPH J. SPENGLER

No quantity can increase by compound interest and remain within finite limits.

—LAWRENCE DENNIS

Man's industrial activities are merely a highly specialized and greatly developed form of the general biological struggle for existence.

A. J. LOTKA

In Megalopolis the sentiment of friendship wastes away.

—R. M. WEAVER

My concern is to put the population question in temporal and statistical perspective. I pass over classical concern lest numbers become excessive and Asian and Roman concern lest they not become extensive enough. I pass over the upward shift of the military and nonmilitary demand for manpower in the Age of Mercantilism and the emergence of a populationist philosophy. I pass over those who after 1750 rejected populationism. I begin with Malthus, at the time of whose birth the world's population numbered just over 750 million, perhaps treble what it was at the start of the Christian era, though growing faster than ever before, now that pestilence had been partially tamed and the supply of the means of existence had become more elastic and more stable.

I. The Malthusian Age: 1800-1930

Malthus may well serve as eponym to the period 1800-1930, since it was he who conceptualized and put into *paradigm* the demographic issues which dominated it. At its start Malthus was warning that an unfettered stork could visit poverty upon most and prevent realization of the aspirations of the Age of Enlightenment. At the period's close the world's rate of population growth was double what it had been in 1800,

* Presidential address delivered at the Seventy-eighth Annual Meeting of the American Economic Association, New York, December 29, 1965. The author is indebted for suggestions to his colleagues, Ralph Braibanti, F. T. DeVryer, C. B. Hoover, and William Yohe.

and its annual increment roughly 22 instead of 4 millions. Meanwhile the world's population had risen from less than a billion to just over 2 billion; that of Europe and the Soviet Union to over a half billion, nearly triple the 1800 figure. Of Europe's population nearly three persons in ten lived in 248 cities of 100,000 and over, compared with only about one in thirty in 18 such cities in 1800. Meanwhile the world's cities of 100,000 and over had risen in number eighteenfold to nearly 700 and their relative population eightfold to 11 per cent of the world total. It is not entirely surprising, therefore, that Alfred Marshall could write in 1920 (*Principles*, preface):

In the present age, the opening out of new countries aided by low transport charges on land and sea, has almost suspended the tendency to Diminishing Return . . . and yet, if the growth of population should continue for very long even at a quarter of its present rate, the aggregate rental value of land for all uses . . . may again exceed the aggregate of incomes derived from all other forms of material property.

Nor is it surprising that Malthus's Geometrical Ratio should be rediscovered in the 1920's [39], and that J. M. Keynes could warn that the Malthusian Devil had broken his chains in a world ridden by diminishing returns. Overpopulated Europe in particular was threatened, he believed. The inequality essential to adequate capital formation was unlikely to be tolerated, and Europe's terms of trade were destined to turn against her, dependent as she was upon produce imported from a New World now become subject to diminishing returns. It was questionable, therefore, if her precarious economy any longer enjoyed a margin of safety against dislocation, a probable sequel to the treaty of Versailles [23]. At least four aspects of economists' response to Malthus's *Essay* in this period merit attention.

1. Malthus's *Essay* directed attention to the critical role of limitational factors and to the impact of adverse externalities associated with population growth. His ultimate limitational factor was land or "room." He implied, however, that it could be some other source of man's living budget, should man practice moral restraint. While England's marginal per acre wheat yield was only 8 bushels in 1812, the average having fallen from 24 in 1771 to 22 in 1812 [8, 2nd. ed., pp. 225-26]. Malthus did not draw upon this sort of evidence. Instead he seems to have reasoned from the limitedness of arable land and its yields to his expositive theorem that the food supply could grow only $1/n$ per quarter-century where n denotes the existing food supply. This model gives a falling average but not finally a falling incremental rate of food and population growth as did P. F. Verhulst's logistic curve, designed in 1838 to reflect the increasing resistance population growth encountered from increasing density and its concomitants.

Malthus's model stressed the services of land. This interpretation is in keeping with K. F. Mather's account of the changes both in man's demands upon his environment and in the nature of his resource limitations. "A hundred years ago, nearly 80 per cent of all the things men used were derived from the plant and animal kingdoms, with only about 20 per cent from the mineral kingdom. Today only about 30 per cent of the things used in industrialized countries come from things that grow; about 70 per cent have their sources in mines and quarries" [25, pp. 55-56]. Some present-day economists, of course, take into account all or nearly all services, the demand for which derives significantly from demand for population. They view economic growth as a process of accumulating capital in all its manifold forms [20, Ch. 14], and population growth as a process of transforming population, physical environment, and capital of all sorts, as of given time periods, into population of subsequent time periods. "Life," as A. N. Whitehead [38, p. 160] observed, thus becomes "robbery," with human societies living on other societies and (as A. J. Lotka noted), having triumphed over their subhuman foes, finding themselves pressed by increasing numbers to struggle with one another. Malthus may thus be looked upon as an inspirer of post-Darwinian as well as of Darwinian theories of struggle. Moreover, Malthus, in his rationalization of essential agricultural self-sufficiency, a doctrine that later helped inspire German agricultural protectionism, reveals himself a defender of bastions of strength against both leveling forces and hordes. "When degree is shak'd," he might have said with Shakespeare, "then enterprise is sick."

Malthus's emphasis upon limitations to the augmentability of the food supply was not reasserted again until the close of the century. For, although natality did not begin generally to decline in Europe until in or after the 1870's, and then not enough to affect the rate of population growth significantly, per capita food consumption improved, both because yield per acre had gradually increased and because food, mainly cereal, was imported in large quantity from land-rich Eastern Europe and Europe Overseas as well as from some heavily peopled parts of Asia [14] [8, 3rd ed., pp. 296-301]. Toward the end of the nineteenth century, one and one-third centuries after England began to import cereals on balance, Sir William Crookes (1832-1919) warned that the question of the food supply "is of urgent importance today, and it is a life and death question for generations to come. . . . England and all civilized nations stand in deadly peril of not having enough to eat." He pointed to the importance of wheat, the lowness of yields, and the limited additional acreage suited to sowing—conditions that would permit world population to overtake world wheat supplies by 1931. Augmentation of yields and acreage prevented

the materialization of Sir William's forecast. J. S. Davis, having reviewed its basis and nonmaterialization, declared in 1932 that "the specter of coming dearth of food is a ghost that deserves to be laid" [13].

The shift in the bias of the resource base from organic to inorganic facilitated a higher rate of development and some economy in transport already near the beginning of the nineteenth century, if not earlier. It did not become pronounced until later in the century, however. Thus, between 1880 and 1937, while world population was growing about two-thirds and its industrial production was almost sextupling, world metal and fuel production increased 606 and 652 per cent, respectively [14] [31, pp. 248-50]. The shift, however, added to the fear of classical diminishing returns, the additional fear of mineral depletion, analogue of soil-fertility depletion. Already in 1865 W. S. Jevons forecasted that rising costs of coal attendant upon the working out of the superior seams would depress British industry and trade [19]. A quarter-century later, there arose even in the United States concern respecting both soil depletion and unduly rapid mineral exhaustion. This concern contributed to the development of the conservation movement later popularized by anti-Malthusian Theodore Roosevelt.

2. Malthus as well as subsequent writers drew attention to the externalities associated with population growth, many of them adverse. A clear-cut distinction was not initially made, however, between externalities produced directly and externalities produced indirectly through urban concentration. Malthus and his successors hoped to control aggregate growth and thus minimize the impact of adverse externalities—through institutional and related controls of private origin, that channeled costs and benefits to responsible and discretionary individuals and households. He had little confidence in Leviathan. In fact J. S. Mill was almost alone in believing that under communism—albeit small-scale communism rather than present-day bureaucratic socialistic or mixed-economy collectivisms—the feedback system generative of population-control would be much more effective than it was under non-communism (*Principles*, II, i, 3). Concern regarding externalities associated with urban growth became both more intense and more research-oriented toward the close of the century. Even Marshall manifested such concern [24].

3. In the wake of this growing awareness of externalities there developed interest in improvement of the quality of populations. While few economists had the faith of a Helvetius or a Bentham in the capacity of education to eliminate inequality, not many attached to reproductive selection the importance assigned it by F. Galton's follow-

ers or by some exponents of Social Darwinism. After all, it was economic environment with which economists worked, and it was their usual view as well as Marshall's that A. C. Pigou [29, pp. 113-14, 121] expressed when, despite his awareness of the importance of genetic selection, he said, "The environment of one generation *can* produce a lasting result, because it can affect the environment of future generations. Environments, in short, as well as people, have children." He inferred, furthermore, that "improvement in the distribution of the dividend may be expected actually to diminish the proportion of the children born from inferior stocks" whose untrammelled propagation remained "notorious." Pigou seems to have been less alert than Ricardo (*Principles*, Ch. 31), however, to the possible depression of the demand for labor, especially among the inferior members of society, by accumulating capital. Otherwise he might have put more stress upon eugenics as well as upon adverse effects of life in large, input-short families.

4. Corollary to Malthus's thesis is the notion that there exists, under given conditions in a given state, an optimum population size and an optimum population growth rate. J. S. Mill was the first to give some precision to the former notion. "After a degree of density has been attained, sufficient to allow the principal benefits of combination of labour," wrote Mill in 1848, "all further increase tends in itself to mischief, as regards the average condition of the people." Such density had been attained in England. Mechanical inventions could, of course, increase average income, but they would increase it even more were numbers not to grow (*Principles*, I, xiii, 2-3; IV, vi, 2). Unlike present-day technicians with their dehumanizingly exclusive emphasis upon *know-how*, Mill was concerned also with *know-why*—he was not prepared to trade natural grandeur, solitude, "the spontaneous activity of nature," and other free goods for the junkyards and carscapes and deteriorating landscapes so characteristic of unaesthetic twentieth-century societies seemingly bent upon frustrating Henry Ford's desire that his car give even the man of little means easy access to "God's great open spaces." Mill would probably have endorsed B. A. Weisbrod's suggestion that account be taken of the willingness of nonusers of facilities (e.g., a park) to pay for the option of using them in the future, given that total revenue from users falls short of costs [37].

Mill's view was endorsed 78 years later by A. B. Wolfe, foremost economic demographer, who declared that "economically, the desideratum is . . . to obtain, in return for whatever expenditure of effort the people may regard as normal and proper, the largest permanently practicable, *per capita* product" [15, p. 68]. The population permitting this would be of optimum size. Wolfe did not accept, any more

than had J. S. Mill, the inference of A. M. Carr-Saunders [6] (and earlier Henry George) that a population normally assumed optimum size. Mill emphasized, as had Jeremy Bentham and others, the need for contraception, a need increasingly stressed during the Malthusian period [18]. Only a tremendous stimulus resulting in an improvement of "signal character," such as had been produced in France by the Revolution, could change men's habits, elevate their standards, and reduce their natality, Mill observed (*Principles*, II, xi, 2); and J. B. Clark (*Essentials*, Ch. 19) 59 years later expressed a somewhat modified version of this view. Not until the 1950's, however, did H. Leibenstein and R. Nelson incorporate a Mill-like view into growth models entailing the displacement of populations from the Malthusian equilibria in which they had been trapped.

The Malthusian period witnessed many improvements in both the art of population projection and the quantity and quality of statistical data, together with the instruments employed to analyze them. A major objective was to eliminate distortions occasioned in crude measures of fertility or mortality by differences or abnormalities in age, sex, and marital composition. Gross and net reproduction rates came into use toward the close of the period, some years after they had been anticipated; they made it possible to determine the rate of increase per generation in a population of stable age distribution, a model developed by A. J. Lotka as early as 1911. The demographer could then cope with changes in age composition associated with adjustment to constant age-specific fertility and mortality rates, though not with unpredictable variations in mortality, fertility, or sex composition [16, Ch. 12]. Population forecasters therefore resorted to projections of present populations based upon various sets of assumed age-specific fertility and mortality rates. Recourse was had also to logistic curves fitted to past populations, a method originated by Verhulst and rediscovered by Raymond Pearl and L. J. Reed, who forecast a maximum world population of about 2,646 million and a maximum American population of about 197 million as of around A.D. 2100 [10].

II. *A Time of Reconsideration: 1930-65*

Opinion on population issues was homogeneous during the period 1800-1930. All but Marxian opinion, whether critical or affirmative of Malthus's views, took his model as a point of departure. Not so in the period 1930-65, or perhaps better, the period 1925-65. Voices were in the breach as Jacob Viner's advice to this body (in 1938), that the economic theorist "is the special custodian for society of the long view in economic matters" (*Am. Econ. Rev.*, March 1939, p. 9) as well as

the discoverer of hidden costs; or Winston Churchill's observation that "a hopeful disposition is not the sole qualification to be a prophet"; or Walter Bagehot's reflection that "it is a question whether the benevolence of mankind does most good or harm" (*Physics and Politics*, Ch. 5).

First of the earlier views to be reversed was that imbedded in the population forecasts (or projections as they now are more cautiously labeled) of the 1930's. Already in 1895 Edwin Cannan forecast a virtual cessation of population growth in England and Wales by 1950. In the late 1920's and 1930's it was inferred that the populations of most Western countries would soon become stationary, the American at a level below 200 million. Even eventual decline was anticipated. Net reproduction rates were near unity, and sometimes still falling. Economists began exploring economic life in hypothetically stationary or declining populations. Publicists and reformers, some of whom may have recognized an opportunity to clothe welfare-state philosophy in demographic terms, refurbished old arguments for a family wage as well as diverse subsidies to parents, with the result that family allowance systems won widespread approval. Inadequately explored in a still-Kiplingesque West, however, were implications of the fact that while the rate of population growth in a politically fissured Western world was falling, that of underdeveloped lands, containing about two-thirds of the world's people, was incipiently high and potentially rising.

By the late 1940's, however, changes in both fertility and population prospects were evident. Not only was death control augmenting natural increase in the underdeveloped world, natality and natural increase had risen in the developed world, in part as a response to rising employment and the emergence of the welfare state. Although fertility later moved somewhat below its postwar peak, population projections were revised upward, sometimes by a factor of 2 or more. Thus the population anticipated for the United States in 2000 was set above 300 million instead of below 200 million [10]. Still, should age-specific fertility move downward, as it now seems to be doing, postulated growth rates will be reduced. Real cohort analysis, designed in the 1940's to replace use of synthetic cross-sectional cohorts, should presently confirm whether current fertility declines reflect a decline in desired family size and signal the advent of a growth rate of only about 1 per cent. In the 1930-70 interval, of course, population will have increased more than anticipated in the 1930's, about 283 million, or 42 per cent, in the developed world, and 1,271 million, or 91 per cent, in the underdeveloped world.

A second reversal of interpretation relates to population growth and capital formation. G. Cassel [7, pp. 134-35, 149] had implied that a 1

per cent rate of population growth absorbs annual savings approximating 5 per cent of national income, but he did not anticipate excessive saving. Such confidence gave way, however, to fear of the advent of a stationary population, despite Mill's earlier description of its advantages. "Investment" (or savings-offsetting expenditure) had been freed meanwhile of its moralistic trappings, and made *a*, and after the appearance of Keynes's *General Theory* in 1936, the strategic variable in employment theory and policy. Given little population growth, investment would be inadequate because provision would no longer have to be made for large population increments, and at the same time there would be too little inclination to invest in improving the environment, quality, and productivity of those already here or replacing those here. This concern reflected an excessive estimate of the difficulties supposedly attendant upon adjustment from a higher to a lower rate of population growth, in an economy made sensitive to the contractile impact of the acceleration principle by a high ratio of reproductive wealth to population. In fact, J. R. Hicks, in his review of the *General Theory* (*Econ. Jour.*, June 1936, p. 252), declared population to be Keynes's "strongest card," and three years later added (*Value and Capital*, Ch. 24) that the "whole Industrial Revolution of the last two hundred years" had been "such a disappointing episode in human history" because (perhaps) it had been "nothing else but a vast secular boom, largely induced by the unparalleled rise in population." Alvin Hansen clearly posed the problems in his address to this body in 1939 (*Am. Econ. Rev.*, March 1940, pp. 1-15), at a time when economists were not yet writing about compensatory public investment in an affluent society. There were critical responses to exponents of stagnation theory, of course, especially G. W. Terborgh's respecting the favorable behavior of investment in a past marked by falling population growth [34], and those of economists who believed that small adjustments in a flexible economy could easily bring annual savings and offsets thereto into balance and assure "full" employment in an economy whether population was growing appreciably or not. Man need not be slave to the stork in the twentieth century any more than he was in the late nineteenth. Ansley Coale [12, p. 371] aptly capped this theme in 1960 when he pointed to implications of current American fertility levels:

Thus a continued secular economic boom could gain partial support from a continued baby boom. But after a century this trend would produce about a billion Americans, and after two centuries some six billion. There must be a better way to stimulate employment.

After all, it should be quite easy to adjust saving and/or offsets thereto,

along with other significant variables, to changes in population size and age composition, both of which are quite predictable in the short run. Until recently, the inverse of the stagnation argument, the thesis that excessive population growth generates inflation, especially in underdeveloped countries, received little attention.

Perhaps the greatest reversal of opinion in the period 1930-65 is that relating to the role played by land and other natural resources in economic development and the disenthraling of populations from Malthusian traps. The importance of this role has been played down for a variety of reasons. First, investment in scientific discovery, applied technology, and education has been found to account for a major fraction of the increase in output per head in advanced countries, although recently the need to complement this type of investment with physical capital has again begun to be emphasized. Second, input of the services of land and natural resources per unit of GNP has greatly decreased in advanced countries. The composition of an individual's consumption changes as his income rises and becomes more biased toward products with relatively small resource content. This is reflected in a below-unity income elasticity of demand for most organic and inorganic raw materials. Furthermore, considerable economy has been achieved in the use of raw materials, with the result that resource-service input per unit of output of many specific types of products has fallen. For example, the input of cropland service per unit of output of agricultural products declined by nearly half in the United States between 1930-32 and 1960-62. In short, changes in the character of both demand and technology have slowed down the growth of various material requirements, sometimes to the pace of population growth and sometimes even below it. Third, discovery and technological change, together with substitution at producer and consumer levels, have greatly augmented both the visible and the immediately potential stock of fuel, mineral, and related sources of natural-resource services. Man, it is supposed, is confronted by chains of natural-resource substitutes which modern molecular engineering and alchemy can subvert to his purposes, replacing links that weaken and elevating inferior sources (e.g., taconite rock) as well as substituting less expensive for more expensive sources of particular natural-resource service needs [1] [33]. For example, energy should prove producible in large amounts through fission assisted by breeder reactors, and in almost unlimited amounts should fusion prove technologically and economically feasible.

A measure of parochialism permeates this optimistic account. It neglects the Apostle Matthew's dictum that "for whosoever hath to him shall be given, and he shall have abundance," and the observation in Deuteronomy "that man doth not live by bread only." Skill and capi-

tal, so essential to overcoming mineral and agricultural shortages, are generally least abundant where needs are greatest. Should income grow as expected in the underdeveloped world, natural-resource shortages will be intensified, probably in greater measure than technical capacity to countervail them. Similarly, diets reportedly are quantitatively and/or qualitatively most deficient in Asia, Africa, and parts of Latin America—in areas commonly short of skill and capital, even when not also of land. There one finds not even a basis for the inverted Malthusianism of Western optimists which equates solution of the population problem with a full stomach. One also finds neglected two income-depressing effects of population growth: (a) absorption of nonagricultural land which might better have supplied man with amenities; (b) steady diminution of the amount available per capita of suitably situated space and goods and services formerly *free*.

Neglected above all is man's conversion of such "parameters of state" as atmosphere, topography, and climate into variables with the result that conditions of life and interspecies equilibrium—never very stable—are changing. Lotka anticipated this possibility in his remarkable *Elements of Physical Biology* (1925). Malthus had treated physical environment as a constant even though man had for many centuries been modifying this environment [35]. But then Malthus lived before the goat had been replaced by bulldozer, dragline, and nuclear explosives, and man had become the most destructive of biotypes. After all, even the physicist, R. A. Millikan, could write as late as 1928: "The energy available . . . through the *disintegration* of radioactive, or any other, atoms may perhaps be sufficient to keep the corner peanut and popcorn man going, on a few street corners in our larger towns," but no more (*Science*, Sept. 28, 1928, p. 284). Today, man is confronted not only by denudation and erosion of soil as well as possible mineral shortages but also by the threat that accumulating filth will convert his promised great society into a merely gray society. Witness here in America endless dumping of trash (four pounds per person per day), lead contamination in excess of that experienced in ancient Rome, and water and air pollution soon destined to cost above \$7 billion yearly. Merely cleaning up the nation's polluted waters could cost over \$50 billion. Indeed, some hold, J. K. Galbraith had better labeled ours an effluent society than an affluent one, perhaps so effluent that many of its members have lost their sensitivity to effluvia. Possibly more threatening still are the changes man is producing "in the geochemical cycles of the elements," thereby "disturbing their natural balance in the uppermost geospheres." Thus since 1900 the carbon dioxide content of the air has risen about 10 per cent and is still rising [30, pp. 365-66, 546-47]. In short, multiplying man, forced by popula-

tion pressure to cope with emerging shortages in his micro-environment, may be worsening his macro-environment and constraining the adaptive potentialities which have gotten him where he is.

Optimum theory has been elaborated and clarified in recent decades. While account has been taken of the content of the welfare index being maximized, it has been noted that output per man-hour may constitute a quite satisfactory index, insofar as deviations from any other index can be resolved through exchange supplemented by taxes. It has been observed also that, while population size may condition a society's capacity for reducing income inequality, it is size of economy much more than size of population which facilitates economies of scale, competitiveness, flexibility, etc. The circumstances governing the response of welfare indicators to variation in population size have been found to include extent of economies of scale, interindustry fit, external economic relations, tastes, technology, length of time horizon, burden of defense or tribute and foreign aid, and so on. Deviation of actual population size from optimum size does not tend to induce a decline in fertility unless this deviation reduces the rate of growth of income below the expected level; this rarely happens in the neighborhood of the optimum, and is not very likely when other income-increasing forces are ascendant. It is possible, of course, that as man's time horizon is extended through prolongation of life and institutionalization of expectations, sensitivity to possible deceleration of income growth increases. Little attention has been given to the stability conditions surrounding an optimum; yet failure to act in conformity with these undermines some of the conditions defining this optimum.

Today emphasis is placed less on the optimum as such than on the broader question: Is additional population growth advantageous? Will it elevate or reduce the rate of growth of per capita income with which other indicators of welfare are highly correlated? Will it contract or extend the range of choice? After all, in much of the world average population density exceeds the optimum level; moreover, many states are too small to accommodate a modern economy, even given a great deal of external exchange. In those countries, moreover, where a larger population would be advantageous, it is highly desirable that increments be added slowly, since a high growth rate sacrifices population quality and equipment to sheer quantity (e.g., in Latin America and Africa). Major issues tend to be examined when inquiry is directed toward assessment of the effects of further growth. Such inquiry led Richard Stone to ascertain how population growth retarded a society's approach to F. P. Ramsey's state of Bliss. It directs attention to the adverse input-absorbing externalities generated by population growth in general and through increasing megalopolitan concentration—usually

in greater measure than associated external economies (if any). It prompts examination not merely of effects associated with short-run allocation and partially offsetting responses to disadvantages of population growth, but also of the longer-run consequences of alternative uses of inputs transformable into population. It reveals how population growth and megalopolitan concentration tend to bureaucratize society and dissipate individual autonomy [32].

The optimum concept has been applied to cities as well as to national populations, though with even less success, because of the heterogeneity of cities. Some attention is also being directed to the advantages and disadvantages of city growth. Much of the work currently done on cities amounts to little more than empiricist inquiry, insensitive to the manner in which distortion of exchange in the urban realm, especially distortion of key exchanges, may distort the urban structure and impose suboptimal conditions of existence upon the passive majority.

Turning from optima to change in population composition, we find two dimensions of increasing concern. The first is age structure. France's population was the first to shed the child-ridden Oriental age structure common to populations in Malthus's day. Modern age structures, together with increases in the proportion of the population over 60-65 years, are concomitants of relatively low fertility; prolongation of life, unless beyond 70, affects this proportion very little. Of course, should it be forgotten that death is essential to progress and should man become immortal, a really Struldbruggian society could develop. For then, given a Gross Reproduction Rate of 1.5, the proportion over 60 would approach 41.4 per cent [11, p. 40]. There would still be a way of escape, however; for, by raising the GRR to 3.0, the proportion aged 60 and over could be held to 9.1 per cent. Man would thus be faced with a choice—between life in a nursing home and life in a sardine can. Fortunately, the bad as well as the good still die, though perhaps in suboptimal proportion. There is need for hardheaded socioeconomic gerontological inquiry into the allocation, employment, income, and related implications of a doubling or more of the fraction of the population over 60 or 65 years since (say) 1870 when only about 5 per cent of the males were 65 or older and many of these lived in nonurban areas.

Perhaps the central economic task flowing from this aging is that of optimizing, over the life span of the representative individual, of his work-time and his discretionary time. Presumably, this arrangement would result in greater vacation time than now—say six weeks per year—and deferment of retirement until age 70. Such arrangement is currently threatened by corporate, trade union, and governmental bureaucrats who, abhorring discriminating decision as the devil abhors

holy water, would fix the age of retirement at or below 60 when one still looks forward to 17-21 years of life. Such a policy would produce an army of endowed, if not particularly happy, loafers. Even in the absence of continuing inflation, decrease in the ratio of work life to retired life by four-sevenths since 1900 entails an offsetting increase in saving for retirement which has not usually been achieved. And even then, as a rule, the retiree does not share appreciably in the fruits of technical progress. Solution consists in part in the re-establishment of flexible, discriminatory wages, periodic worker retraining, possible job reassignment, portable retirement provisions, price stability, and an evolution in work scheduling. The alternative could be a variant of Townsendism.

The second problem-ridden structural change accompanying population growth is not mere urbanization (which within 30 years, according to K. Davis, will gather over half the world's population into cities of above 100,000), but the concentration of so large a proportion of the population in megalopolitan centers which appear to be uneconomic devourers of time and capital as in the past they were devourers of population. This concentration appears to be the product of an indeterminate mechanism, made up in the part of random variables and fostered by disparities between social costs and social benefits as well as by neglect of adverse externalities associated with concentration. In short, the urban growth pattern may be stochastically determined, with chance working on the side of the largest centers and in keeping with Zipf's generalized Paretian, or rank-size, "the-higher-the-fewer rule." Here we may not have a causal mechanism operative, since, as M. G. Kendall [21] notes, "chance can mimic choice," nor do we have simple, unlagged cause-effect relationships [22]. There could, of course, be something like G. Myrdal's cumulative causation at work, or perhaps a cumulative process somewhat analogous to that described by W. J. Baumol in his "theory of cumulative deterioration" [2].

What is of immediate concern, however, is whether the mechanism at work produces an optimum distribution of activities in space and of population among cities. The outcome, whether good or bad, is almost irreversible, underpinned as it is by fixed capital, special interests, inertia, subsidies, and so on. That the outcome is optimal is to be doubted despite the clamor of hyperurbanists. They forget that vulnerability to attack by missile and from the air is positively associated with population concentration. It is essential that one take into account *all* costs as well as *all* benefits associated with large-city expansion, so remindful of the growth of polyp colonies; only then is the marginal net effect ascertainable. Excessive concentration of population in large cities not only tends to dissipate *gemeinschaftliche* ties, and generate

alienation; it is also inimical to individual-political and consumer sovereignty. Mathematically, the larger the city, the smaller is the relative size of the resolute minority that could rule it [28]. Politically and psychologically, the larger the city, the weaker tends to be the belief of the voter that he can do anything to influence the ruling camarilla and improve his community. Finally, as political power is channeled into the hands of city-ruling minorities, the taxing power of the central government tends to be placed increasingly at the disposal of these minorities and perhaps in keeping with what one may call the Augustus Caesar principle of public finance. (You will recall Seutonius's account. Caesar once considered discontinuing the practice of distributing free grain, but he decided against it even though it was injuring Italian agriculture. "I did not carry out my purpose," he said, because I felt "sure that the practice would one day be renewed by someone ambitious of popular favor.")

While notable contributions have been made to the economic analysis of fertility [3, 12], the explanation of its short-run behavior has not yet been made as economic as possible, nor have the actual and the potential feedback connections of household with economy been adequately identified and explored. If one allows for random variables and treats certain fertility-affecting elements (religious and other values, rural-urban and educational differences) as short-run constants, one should be able to explain changes in gross reproduction in terms of changes in price structure and opportunity costs and of movements along curves of demand for children and of shifts of both these curves and curves representing costs of children. For a change in fertility reflects the response, usually lagged, of actual and potential households to changes in (a) the prices and character of alternatives to children, and (b) the benefits anticipated to be derivable from children and/or changes in the input costs of children, together with additions (subtractions) in costs associated with changes in family economic status. It must be assumed, of course, that fertility is easily controlled. This assumption is quite tenable in advanced countries, now that earlier contraceptive methods, including the unreliable "safe-period"—in Spain children who owe their existence to failure of this method are eponymously described as *Oginitos* after the method's discoverer (*New Leader*, Sept. 13, 1965, p. 7)—have been supplemented by contraceptive pills and cheap, effective intrauterine devices. It is essential also that the analyst view the child as the partial analogue of both a consumer's and a producer's durable good. Then the analytical as well as the empirical problem becomes one of isolating the determinants that affect the demand for, and the supply of, children at household levels, and thus give rise, along with household interdependence, to aggregate demand and supply functions.

The demand for children is not quite parallel, however, to that for ordinary durable goods. The relevant time interval is too long to permit a household to test *ex ante* expectations respecting children by *ex post* experience. No one can foresee what the genetic grab bag will bring forth, probably a useful citizen, possibly a genius, perhaps a hooligan or a cretin, but by then corrective response may no longer be possible. There is less uncertainty, of course, on the supply side. Most direct costs are fairly predictable, and optional additional costs need not be incurred unless they fall short of the prospective benefits. Less predictable is the impact of trade and longer cycles, or of increases in unemployment consequent upon upswings in the relative number of young job-seekers, cobweb-like sequels to earlier upsurges of births [12]. Less predictable also, especially in a modern demand-oriented economy, is the response over time of a household to its increasing access to durable goods and imperfectly foreseen complements thereto. For in this sector of consumption the income elasticity of demand can easily rise above unity and, if this rise is widespread enough, divert income from support of procreation to purchase of durable products and complements. The full significance of the emergence of durable goods for reproductive and other activities has yet to be analyzed adequately. Indeed, the Ford Foundation might fund a project permitting a corporate body of social scientists to follow through life a representative cohort, or better still a sequence of cohorts chosen at (say) 10-year intervals, and ascertain how and why patterns of expenditure change and with it fertility and related behavior.

Underdeveloped countries, United Nations demographers find, differ from developed in respect of both fertility and indices of modernization. Gross reproduction is below 2 in all developed countries, and above 2 in the underdeveloped world which includes nearly all African, Asian, and Latin American countries. Within the modern world there is no correlation between variation in indicators of modernization and variation in fertility; and within the underdeveloped world there is only slight correlation. The data do suggest, however, that there exists a threshold, or a set of thresholds, movement beyond which by indicators of modernization is quite likely to be accompanied by a perceptible downward movement of fertility, though not by one immediately adequate to offset falling mortality.

Convincing evidence of a widespread, imminent, and pronounced decline of fertility and natural increase remains to be uncovered. The United Nations reports: "the launching of new countries upon the transition from high to low fertility seems to have been temporarily halted." The evidence reveals no continuing inverse relation between population density and fertility in keeping with the logistic theory; only a mildly inverse relation is found in both the developed and the

underdeveloped world. The pressure of numbers upon family resources generated by the decline of infant and child mortality has not yet widely reduced births per mother. Governments not only show little awareness of the urgency of the population problem; they even cushion the incidence of child-rearing costs on responsible parents. The Economic and Social Council of the United Nations, together with individual countries, has sanctioned making contraceptive assistance internationally available, but governments have provided little incentive thereto [36].

The economic implications of United Nations studies of fertility and population growth are at least fourfold. First, for a number of decades population growth will absorb large amounts of physical and personal capital that might otherwise have been used to elevate per capita income. For example, *ceteris paribus*, per capita income can grow at least one percentage point more per year, given a zero instead of a two-per-cent-per-year rate of population growth. Second, little explanatory insight is provided by economic models which merely suggest that income will permanently outstrip numbers, but which are unequipped with feedback mechanisms that produce at least limited downward movements of fertility. It is necessary to show that movements of income generate even greater relative demands for present and future goods, services, and leisure; that elasticity of consumption expectations exceeds elasticity of income expectations. Then, if the standard of life rose ratchet-like, but always guarded against decline by pawl-like acquired tastes, one might count upon the retention of internalized standards. Third, the apparent existence of a set of interrelated thresholds suggests that international differences in shorter-run fertility-affecting constants are dissipatable through subjection to socioeconomic solvents. Fourth, even though these parametrical differences exist, it is certain that fertility can be greatly reduced, given availability of contraceptives, if having more than a stipulated number of children, say three, is economically penalized instead of subsidized as at present. That it would pay the governments of underdeveloped countries to reward those who curb their fertility has been demonstrated by Stephen Enke who estimates one dollar thus spent to be worth about \$100 of other forms of aid [17].

III. *The Future*

Technology, prudence, and reason could generate a bright future. That it will be bright, however, is questionable, given an unfettered stork, together with continuing escalation of submarginal man in a world of Freudian irresponsibility and distribution according to al-

leged need rather than demonstrated performance. Just as relative immunity of an organ's cells to division and mutation causes that organ to age, so does the relative immunity of a society to rigorous selection tend to bring about its deterioration. It may be well, however, for one interpreting these portentous trends to recall what Samuel Johnson wrote in the preface to his dictionary about the prophecies he had made earlier in his launching prospectus: "I . . . now begin to fear that I have indulged expectation which neither reason nor experience justify." Yet, mankind does appear to be at a demographic crossroads, along which weak homeostatic response under current conditions may not properly direct man. Population growth still resembles too closely Newton's "uniform motion in a straight line," unrelieved by the prospective emergence of fertility-controlling "impressed forces."

Consider India. Down one of the crossroads could lie a sanguine future. For, as S. J. Patel suggests, the economic distance between India and present-day America might be bridged, though hardly in a half-century; the difference between Indian and American real agricultural output per capita could be removed in some 50 years; that in other sectors, in a longer period. Yet, as Coale and Hoover have shown, there can be little improvement in the average Indian's lot if India persists down the road of population growth [26].

More generally, to paraphrase President Kennedy's warning against war: Unless man halts population growth, population growth will halt man. As matters stand, two demographic processes are bound to bedevil man increasingly and, if they are not soon resolved, will greatly diminish whatever prospect he has of establishing a society both peaceful and great, both moral and aesthetic. These two processes are continuing population growth in a finite world and increasing concentration of people in progressively larger megalopolitan centers. Progeny and space will have to be rationed much more effectively in the future than in the past.

The more remote prospect is bleak while the immediate prospect, blurred by current income growth, is misleadingly hopeful. Population growth—demographic entropy—is dissipating man's capacity for maneuver much as economic entropy is dissipating the utility locked up in depletable natural resources. After all, increase in number is an essentially irreversible process; men usually multiply, but they seldom dwindle as did avian, mammalian, and other species now extinct. Even in the United States should natural increase plus a prospective annual immigration of 350,000 long continue to increase population 1.0-1.5 per cent per year, our population, 325-350 million in 2010, would number 0.8-1.33 billion by 2100, and 1.5-2.8 billion (with perhaps one-fourth nonwhite) two centuries hence. Acres of land of all sorts per

capita, probably still close to 5.5 in 2010, would continue to decline until there would hardly be space even for our national flower, the concrete cloverleaf. Aesthetic considerations of all sorts would be swamped by masses instead of by costs masquerading as pseudo-utility as at present. Even in the absence of strepitous poverty-mongers many would be conscious of being poor.

An even worse prospect obtains in the world at large. Between 1960 and 2000, according to United Nations estimates, world population will grow nearly twice as fast as in 1920-60—around 113 per cent to between 6 and 7 billion. The proportion in the developed world will fall to around 22 per cent, since its numbers will grow only 61 per cent, or but two-fifths as fast as the population of the underdeveloped world which is expected to increase about 151 per cent. Should world population continue to grow about 2 per cent per year it would number 16-18 billion by 2050 and 43-50 billion by 2100. Even if it should proceed only 1.5 per cent per year it would number 13-15 billion by 2050 and 26-31 billion by 2100. Acres of all sorts per capita, still about 4.7 to 5.5 in 2000, will then have fallen to 0.6-1.25 by 2100, and close to one-half of this amount will be unfit for habitation except by Lower Slobbovians. Man will have become essentially spaceless in a space age, unless competition for living space should accidentally transform the "ultimate deterrent" into the "ultimate detergent" and, as D. M. Heer estimates (in his *After Nuclear Attack*), destroy perhaps 30 per cent of the population, mostly in heavily urbanized areas.

Given growth of the order suggested as likely in the absence of concerted efforts to limit numbers, food shortages would eventually develop despite schemes for deriving protein from coal and petroleum as well as subsistence from algae and other crude organic matter, or for supporting a man on 20 well-cultivated square meters of soil. First, cultivable land is limited, though only about 7 per cent is used for non-food crops, mainly fibers. In 1964 arable and permanent-crop land totaled about 3.6 billion acres; land in permanent meadows and pasture, about 6.2 billion acres; and land in forest, about 10 billion acres. Just how much land in the two latter categories is convertible into crop land is indeterminate, though subject to exaggeration. It depends upon technology, upon mastery of cultivation in the tropics and in droughty and cold regions, upon land clearing and development, often a costly process, and upon adequacy of the water supply. From the gross amount of land so converted must be subtracted land blotted out of agriculture by creeping concrete, construction, city growth, etc., which in the United States has amounted to one-half acre or more per inhabitant added to the urban population.

Second, though average yield per acre could prove capable of 300 or

more per cent increase, crop yield per acre is limited. Yield increases are promising, of course. After all, "over a large part of the world today agricultural productivity is now the same as, or even inferior to, what it was in the leading civilized communities 2,000 years ago" [9, p. 78]. Yields per acre vary widely; thus Japan produces roughly 3-4 times as much rice per acre as do South and Southeast Asian lands. This variation is associated mainly with variation in input of fertilizer, addition of a kilogram of which may increase grain output about 10 kilograms, given suitable methods of cultivation. Developed countries use 5 times as much fertilizer per acre as do the underdeveloped; Europe uses about 20 times as much as do Africa and Asia and 9 times as much as does Latin America; Japan uses over 100 times as much as do India and Pakistan.

In many if not most underdeveloped countries pre-takeoff conditions essential to the great upsurges in yields experienced in the United States, Britain, and Japan have not yet been established [5]. Nor are they soon likely to be established, given excessive population growth and heightened barriers to the detraditionalizing of agriculture. Yet, as James Bonner shows, even if a takeoff is experienced, it cannot carry average production per acre above the limits "determined by the factors that regulate photosynthetic efficiency" and "being approached today . . . in parts of Japan, of Western Europe, and of the United States" [4, p. 14] [5]. Within limits, of course, the amount of nutrient supplied per acre can be augmented through recourse to higher-yield crops (e.g., soya beans).

The future of the food problem may be stated simply. Suppose we increase world output 700 per cent by doubling crop acreage and quadrupling yields. World population would catch up with this increase in about 107 years, given an annual growth rate of 2 per cent, and in about 140 years, given a 1.5 per cent rate. Trebling crop acreage would add perhaps a quarter to the above output, but only about one-tenth to the years of grace. Rationalization of fisheries would not change the data significantly. Augmentation of the food supply in the measure indicated is unlikely. This is not *one* world; requisite knowledge and its necessary complements are not likely to be imported and assimilated rapidly in backward lands; nor will progressive lands have incentive to export food, mainly cereal (of which about 5 per cent net is redistributed by international commerce) to exchange-short countries.

Turning from land, the principal source of man's food and the sole source of his living space, to water and minerals, the other primary ingredients of man's material well-being, one encounters limitations parallel to those of land. A precise measure of these limitations is not available. It depends on rates of consumption which are rising, upon actual

and exploitable reserves which remain underinventoried, and upon man's ability to develop substitutes for current sources. Even so, the outlook is not as promising as our Indian Summer natural-resource experts would have it. Consider water, long the economist's standard exemplar of a free good. We Americans use in all forms over 370 billion gallons of water per day and by 2000 we shall require 900 billion gallons, which probably can be provided out of the 700 billion available of the 1,200 billion that daily flow to the sea [40]. This amount, together with what is otherwise required and used of an average daily rainfall of about 5 trillion gallons, will not suffice beyond the present century. Then we shall have to reduce our average consumption, so imbedded in our mode of living, since it is improbable that desalination of sea water can add greatly to our supply of appropriately situated water.

The long-run availability of large-volume materials (e.g., steel, aluminum, concrete, ceramics, glass), together with our ability to cope with shortages of special small-volume materials, depends, as F. G. Tryon [15, pp. 136-38] suggested 40 years ago, upon man's ability to produce and appropriately distribute cheap energy. Under present conditions and at prospective use rates, the world's exploitable reserves of a number of minerals will last less than a century. Aluminum and iron would last 4 centuries at recent use rates, and the key fertilizers, potassium and phosphorus, much longer. The World Power Conference of 1962 put economically exploitable coal reserves at 3.5 trillion tons, enough for 800 years at current annual world consumption rates (about 4.4 billion tons in 1960) and 100 years at American rates. Other fossil fuels will last only into the next century. Water power could supply the equivalent of 2.5 billion tons of coal per year, or less than half current world energy consumption. Given breeder reactors, usable uranium might come close to supplying as much energy as current mineral or fossil fuel reserves; and low-grade thorium could supply 10-20 times as much. Fusion, when it becomes manageable, could make the supply of energy virtually inexhaustible, even in the absence of tidal, solar, geothermic, and related sources [27] [33, pp. 74-97]. In short, given the cheap energy likely to be available, shortage of space, land, and water rather than of minerals would check the growth of population and living standards. Limits will be imposed also, of course, by unavoidable shortages of skilled personnel. Even given requisite natural talents, we cannot long increase skilled manpower faster than population; otherwise the whole of the labor force will be transformed into economists, engineers, physicians, and other categories of skilled manpower, and none will be left to minister to other wants.

I have just been concentrating upon what exponential growth can do in a finite environment, upon a growth process which, as Coale reports [11, p. 36], within 65 centuries and in the absence of environmental limits, could generate "a solid sphere of live bodies expanding with a radial velocity that, neglecting relativity, would equal the velocity of light." Let me now recall that second process operative in our world of shrinking space, a process to which man must respond even as the ratio of suitably situated space to population declines. I refer to that seemingly stochastic process which is concentrating an ever larger fraction of the world's population within the confines of a small number of megalopolises or human rabbit warrens. This process accentuates the adverse externalities associated with population growth and, as has been suggested, may produce unfavorable political effects as well as frustrate the demand for living space which tends to rise with income. But let me turn to solutions.

Curbing population growth could prove easy in modern nations, given current contraceptive methods and knowledge thereof. It is necessary only to alter the terms of trade between gross increments to the population and alternative uses of the inputs involved. In essence, this might entail holding each couple responsible for all or most costs, visible and invisible, direct and indirect, of reproducing and rearing children, in keeping with at least minimal standards prescribed by the state. Should the number of births still be too large, excise taxes could be imposed upon higher-order children and upon child-oriented products and services, while if births were too few, these products and services could be cheapened through use of subsidies.

Control of megalopolitanization and the redirection of urban growth are achievable through use of taxation, penalties, and constraints. Initially, however, much more study needs to be made of longitudinal and cross-sectional relations between variation in city size and marginal cost-benefit ratios under essentially comparable conditions.

As matters stand, the longer-run prospect is definitely Malthusian, with man sitting on a demographic time bomb into which legislators, and others, here and abroad, continue to shovel combustibles. Yet there may be grounds for conditional optimism. Not only can economists devote to the population question more attention than they gave it in the past 80 years when they devoted only about 1-1.5 per cent of their articles to population,¹ but there are many more economists to do the job. Today more economists are practicing than lived and died in the past four thousand years, and their number is growing even faster than the world's population.

¹ This estimate is based upon entries in the *Index of Economic Journals*, sponsored by the American Economic Association.

AN INTERNATIONAL COMPARISON OF THE TREND OF PROFESSIONAL EARNINGS

By TIBOR SCITOVSKY*

I

The purpose of this paper is to assemble and present in comparable form some of the statistics available on professional incomes in a number of Western countries. The professions selected are the law, medicine, dentistry, the higher civil service, and higher learning; the countries are Canada, Denmark, France, Germany, Norway, Sweden, the United Kingdom, and the United States. An attempt has been made to carry the data back to before World War I whenever possible.

My interest in professional incomes has been aroused by the alleged and oft-cited connection between economic growth and the advance of democracy on the one hand and the worsening economic status of the intellectual and professional classes on the other. This trend has been noted not only in the United States but in most Western countries; it explains the springing up, all over Western Europe, of organizations of intellectuals and university graduates, aimed at defending their interests and drawing the public's attention to their plight. In Canada, in the 40 years between 1911 and 1951, the income of professional people is estimated to have risen only one-quarter as fast as the income of industrial workers; in Germany, over a period half as long (1936-55), the average income of the free professions is said to have risen by half as much as the income of the rest of the economy [4] [5]. The same trend, though less pronounced, is present also in Great Britain, where, between 1911 and 1956, the average income of the liberal professions has risen by two-thirds of the rise in the national income per head of occupied population. (Cf. Col. 16 of unpublished appendix table on U.K.)

Perhaps the first person to notice and analyze this phenomenon was Alexis de Tocqueville. In his *Democracy in America* he remarked and

* The author is professor of economics at the University of California, Berkeley. The data presented in this paper were collected during his tenure of a Ford Faculty Fellowship in 1957; and he is also indebted to many people in Denmark, England, France, Germany, Norway, Sweden, and the United States for helping with the search. The Institute of Business and Economic Research at the University of California, Berkeley, generously provided research assistants for this and other projects; and the author owes a special debt to Mary H. Hager, his research assistant who did the most work on this paper.

speculated upon the lesser disparity in the United States than in France, and in the France of his day than in that of Napoleon, between the salaries of high civil servants and that of office messengers.¹ He explained the difference in these disparities by differences in the degree of democracy—more democracy in America than in France, and more democracy in the France of 1833 than in that of 1810. According to Tocqueville, an aristocracy tends barely to allow a subsistence minimum to office messengers but to vote high salaries for the high offices of State, positions which they or their children might occupy and benefit from; whereas the people, when they govern, are generous toward the humbler public officers but envious of and niggardly toward the higher ranks. He might have found his explanation even better confirmed had he known that by the mid-twentieth century these income disparities were to decline very much further in France but change little in America; and had he also known that, of the Western countries, the British pay the highest and the Swiss the lowest salaries to their high civil servants (Table 1).

Tocqueville's political argument might be carried a little further. In aristocratic and feudal societies, great disparities between the salaries of high and not-so-high civil servants have also served to restrict entry to the profession and make it a preserve of the well-to-do. For the way to the high offices of State leads through the middle ranks; and if the pay in these is insufficient to enable officials to maintain the standard of living expected in their station, then the way to the higher ranks is blocked to all but those who at this early stage can supplement their pay out of private income. An example of this has been until not so long ago a branch of the civil service in Germany and other Central European countries—the academic profession. A university professor earned as high an income as the highest ranking civil servant; but he attained this income and the accompanying high prestige late in life, and until then held the position of *Privatdozent*, a title with no, or virtually no, income. Hence the need in those days and in those countries for a private income as a prerequisite for an academic career.

The political factors, however, tell only part of the story of civil service pay and are no help whatever in analyzing the earnings of the free professions. For a full explanation of the level and trend of professional incomes we need economic explanations as well. The most important of these, probably, is the increasing availability of higher education and its diminishing cost to the individual. This, too, has to do with democracy, of which it is one of the main aims and achievements; but it is democracy exerting its influence through economic channels. The

increasing availability of higher education has increased the supply of people eligible for the professions and has thus tended to lower professional incomes (Table 2).²

(1) Sources: F. Edding, *Die Ausgaben fuer Schulen und Hochschulen im Wachstum der Wirtschaft*, Pt. II, Kiel 1957, p. 94; *Biennial Survey of Education in the United States*, "Statistics of Higher Education," 1957-58, p. 7. Coverage: "Institutions with courses creditable toward bachelors' or higher degrees," including less than 3 per cent "Technical Institutions and semiprofessional schools" such as teachers' training colleges, etc. Figures are for full- and part-time undergraduate and graduate students.

(2) Sources: F. Edding, *op. cit.*, p. 43; For later years: Canada, Bureau fédéral de statistique, *Aperçu biennal sur l'enseignement au Canada*, Pt. II, Relevé de l'enseignement supérieur, 1950/52, pp. 56-57; 1956, Canada, Bureau of Statistics, *University and College Enrollment*, Fall 1955, p. 5. Coverage: Universities and colleges other than teachers' training colleges. According to the English version of the Biennial Survey used by Edding, figures are for full-time students throughout while its French version describes them as including part-time

² The increasing supply of trained and educated people is also attributed to technical progress increasing the demand for training and education. Neutral and uniform technical progress raises all earnings in proportion and hence raises the return on education, expressed as the (absolute) difference in earnings between the skilled and the unskilled. If education is among the uniformly progressing industries, the gap between the cost and return on education is widened, thus raising the demand for it [1, pp. 53ff.].

It is true that, hand-in-hand with the increasing availability of education, educational requirements for eligibility to the professions have also been raised, tending to restrict supply. Where of old anyone could hang out a shield and practice his profession, now diplomas, licenses, and many years of training are required. Mostly this represents a welcome protection of the public; in some cases the desire to raise incomes by restricting numbers has also played a part. Both factors have probably been present in medicine in the United States, where alone among the countries considered, the limited number and capacity of the medical schools and their strict admission requirements have reduced the ratio of physicians to total population over the past 60 years. In all other countries and all other professions considered in this study, the relative number of professional people has increased over time.

The importance of the supply of professional incomes is also suggested by an international comparison of these two quantities, shown in the scatter diagram of Figure 1. Along the vertical axis is measured the salary of a highly paid natural scientist, the head of the national meteorological service, expressed as a multiple of an office-messenger's pay; along the horizontal axis is measured a rough index of the supply of professional training, the number of students enrolled in universities and institutes of technology per 100,000 of population. The correlation

enrollments for the postgraduates; however, the possible error is small, postgraduate enrollment being roughly 5 per cent of undergraduate enrollment before 1952 and 7 per cent in 1952. For the 1956 figure, there is no indication whether part-time enrollment is included or not.

(3) Sources: F. Edding, *op. cit.*, p. 81; United Kingdom, Central Statistical Office, *Annual Abstract of Statistics* 1960 (No. 97), p. 100. Coverage: Full- and part-time university students taking courses.

(4) Sources: F. Edding, *op. cit.*, p. 35; *Annuaire Statistique de la France, Rétrospectif*, 1961, p. 67. Coverage: "Enseignement supérieur public, effectif des étudiants français et étrangers."

(5) Sources: 1956, *Statistisches Jahrbuch fuer die Bundesrepublik Deutschland*, 1957, p. 94; 1950, *ibid.*, 1952, pp. 70-71, 1935, *Statistisches Jahrbuch fuer das Deutsche Reich*, 1936, pp. 544 and 549; 1929, *ibid.*, 1930, pp. 454-60; 1913, *ibid.*, 1914, pp. 316-21; 1909, *ibid.*, 1910, pp. 276-78. Coverage: Universities, "Technische Hochschulen" and other types of "Hochschulen," excluding teachers' training institutions. The 1956 and 1950 figures are for "Immatrikulierte Studenten," and the earlier figures for "Studierende" excluding "Hoerer and Hospitanten" which gives a fairly consistent time series.

(6) Sources: F. Edding, *op. cit.*, p. 59; 1947, Sweden, *Statistisk Årsbok*, 1949, pp. 275-76. Coverage: "Institutions of Higher Education" which means Universities and various types of "Högskolorna."

(7) Sources: 1957, Norway, *Statistisk Årbok*, 1959, p. 251; 1950 and 1939, *ibid.*, 1953, p. 254; 1930, *ibid.*, 1931-32, p. 163; 1920, *ibid.*, 1920, pp. 183-84; 1910, *ibid.*, 1911, p. 175 and *ibid.*, 1910, p. 146. Coverage: "Universities and Equivalent Institutions."

(8) Sources: 1956, Denmark, *Statistisk Årbog*, 1957, p. 235; 1950, *ibid.*, 1951, p. 223; 1945, *ibid.*, 1947, p. 180; 1940, *ibid.*, 1941, p. 165; 1935, *ibid.*, 1937, pp. 153-54; 1930, *ibid.*, 1933, pp. 132-33; 1915, *ibid.*, 1920, p. 174. Coverage: The tables were for "Students in Institutions of Higher Education, Senior Vocational Schools, etc." and some of the enrollment figures had to be subtracted out to obtain a coverage that seemed reasonably comparable to that in the other European countries considered.

FIGURE 1

is striking and could go a long way toward explaining the very great national differences in salary differentials.³

Having discussed the influences on professional incomes from the supply side, we must now turn to those exerted on the side of demand. First, the rise in real incomes that results from economic growth tends to raise demand for most consumers' goods and services, including professional services. Second, the increasing complexity of our civilization has created a demand for a whole range of new professions and occupations that require extensive scientific and technical training and thus compete with the older professions for the available supply of highly educated and trained manpower. These two factors tend to boost professional incomes and thus to counteract the depressing effect of the increase in supply.

A third factor, but one likely to exert a downward pull on the demand for professional services, is the probable lag in the productivity of professional people. The rise in incomes tends to raise the demand

³ On the other hand, the correlation could also be explained by the much greater international mobility of natural scientists than of office messengers, which would account for the much lesser absolute differences in the earnings of natural scientists. It seems likely that earnings in mobile occupations should be roughly the same in different countries, while in immobile occupations they should be quite different, higher in rich and lower in poor countries.

for goods and services because the prices of these rise either not at all or more slowly than incomes. The faster rise of earnings than of prices measures the rise in the productivity of labor; and unequal advances in the productivity of different industries and activities create changes in the structure of prices, in the pattern of demand, and also in the structure of incomes and earnings. In fields where the productivity of labor has made the greatest strides, product prices fall the most relatively to earnings and the prices of other products; in fields where labor productivity has not risen at all, product prices remain unchanged in relation to earnings in the same field but rise in relation to the prices of other products.

The productivity of professional people is notoriously very difficult to measure, because changes in the quality of professional services, in medicine for example, can be major and must be taken into account. In many professions, however, these changes cannot have been great, and productivity is likely to have advanced less than that of most other types of labor. If this is so, and if this trend has not been counterbalanced by increasing disparity in the length of the working week of professional people and others, then one would expect the prices of professional services to have risen relative to the prices of most other goods and services; and this relative rise to have discouraged demand for the services of professional people. This force, then, goes counter to the stimulating effect of rising real incomes on the demand for professional services.*

Yet another factor very different from those so far discussed but believed to have a great influence on professional incomes is inflation. The incomes of the professional groups here considered are determined to some extent by tradition. The members of these professions traditionally believe and like others to believe that they are rendering essential public service, the price of which is determined by factors other than their bargaining power in the market place. This tradition inhibits them and their professional organizations in seeking to maximize their incomes and explains why these respond sluggishly to market forces and may have a range of indeterminacy within which they do not re-

*One is unduly tempted in this connection to focus attention on the relation between the prices of professional services and the average level of money incomes, expecting demand for these services to rise if their prices fall and to diminish if their prices rise in relation to average incomes. The logic of this argument is best seen in the simple case of a parallel rise in money incomes and the prices of professional services. If the prices of other goods and services stand still or increase more slowly, *real* incomes will rise and stimulate the demand for professional services; on the other hand, the slower increase of other prices implies a rise also in the *relative* price of professional services, which discourages the demand for them. There is no reason to expect these contrary forces to offset each other exactly.

spond at all. Hence the belief that inflation lowers the real incomes of the professions.

This argument is probably valid at a time of small price increases or at the beginning of an inflationary period, and especially with respect to salaried professionals. The experience of more severe and more prolonged inflation, however, shows that market forces protect the interests of the so-called fixed-income earners as well as those of any other group. France's civil service (which includes teachers and professors) is protected no less effectively than organized labor by an escalator clause linked to the cost-of-living index; and in Chile, white-collar workers and the professions are supposed to be among the beneficiaries of inflation.

Prolonged inflation might nevertheless hurt the salaried professional groups whenever market forces are against them. For their salaries, once set, are not likely to be reduced in response to a fall in demand or rise in supply, and may remain at a higher level than the forces of supply and demand would justify. In such cases, an inflationary price rise may be necessary for market forces to exert their downward pressure on the real incomes of these groups. In other words, inflation can hurt fixed-income earners by *enabling* market forces to overcome the downward rigidity of salary scales.

While it is easy to list factors that influence the demand or supply of professional services, it is difficult to appraise their relative importance. All I could do and have done was to give data on the earnings and numbers of people in the free professions, in an attempt to furnish the coordinates of the point of intersection between supply and demand curves.⁶ A third bit of information, the length of the working week, was not available; but a guess at least can be made. U. S. data for a part of the period suggest that the secular shortening of the working week was largely confined to workers and clerks. Businessmen, managers, officials, and professional people work a longer week and one that has not become appreciably shorter over the years. In relative terms, therefore, compared to the rest of the occupied population, the length of the professional person's working week has increased—and the trend was probably similar in the other countries too.

II

In an international comparison of this type, the main problem is to obtain comparable data. National differences in the availability, the

⁶ No data are given on the number of people on university faculties and in the civil service, owing to the difficulty of obtaining comparable series on comparable definitions. The same difficulty explains why the income data are confined to only one rank in the hierarchy; and it seemed meaningless to give the number of persons in that single rank.

sources, the derivation, and the definition of the data were so great that an originally more ambitious project had to be cut down drastically. The number of countries, professions, detail, and types of data covered is much smaller than originally contemplated; and many compromises had to be made in presentation for the sake of better comparability. To compare professional earnings over time and between nations, it would have been desirable to express them as multiples of an over-all national average of personal incomes per employed population—we had to settle instead for multiples of *national* income per *occupied* population or labor force. Another interesting comparison would have been that between the absolute levels of professional real incomes in different countries; but official exchange rates would have been too crude and misleading, purchasing power equivalents were available only for a single year, so here, too, we had to settle on a mere fragment of what was originally contemplated, the few data contained in Tables 3 and 4. We also hoped to present data on all ranks of academic faculties and professional civil servants but the difficulties of international comparability proved insurmountable—hence the limitation of data to full professors and the highest ranking permanent civil servant.

Despite such compromises and narrowing of the scope of the study, full comparability of the data has not been achieved. The most important of the unresolved difficulties in this respect stems from differences in the provenance of the earnings data of the free professions. In the United States, estimates of the professional earnings of physicians, dentists, and lawyers are based on questionnaire surveys, with the re-

TABLE 3—AVERAGE EARNINGS OF EUROPEAN PROFESSIONALS AS A PERCENTAGE OF THE PURCHASING POWER EQUIVALENT OF UNITED STATES PROFESSIONALS FOR 1955*
(European weights)

Country	Physicians	Dentists	Lawyers	Professors	Civil Servants	Per Capita Income
Denmark	43		62	58	39	49
United Kingdom	67	79	81	110	141	55
Norway	36		67	72	43	62, 51
France	65	114		80	52	53
Germany	47	49	84	123	110	57

* Where 1955 data were unavailable, comparisons were based on 1950 data. These are in italics. Purchasing Power Parity rates were calculated from Tables 5 and 8 of Milton Gilbert, *Comparative National Products and Price Levels*, Paris 1958.

Earnings data are from the unpublished appendix tables. Earnings of free professionals in Denmark, Norway, and Germany have been increased by 20 per cent, in the United Kingdom by 10 per cent, for an estimated understatement of income.

The estimate for dentists' earnings in France is probably too high.

TABLE 4—AVERAGE EARNINGS OF EUROPEAN PROFESSIONALS AS A

^a The notes of Table 3 apply *pari passu* also to this table.

spondents assured of anonymity and guaranteed against disclosure of the information furnished. The French estimates are derived partly from tax, partly from other, data, reconciled and rendered comparable by correcting for an estimated 33 per cent understatement of income in tax returns. In the other five countries, the estimates are based on income tax statistics without correction for understatement and are likely therefore to be too low—in a ratio presumably different for the different countries and perhaps also for different dates. For tax evasion probably increases with the burden of taxation, which is on the increase everywhere; and it is likely to be less important in a well-policed country like England, where payments into a physician's bank account are a source of information on his gross professional receipts.

It seemed impossible to correct the data for such differences; but their order of magnitude may be gauged by the discrepancy between U. S. income-tax and questionnaire-survey data in the few years for which both are available.⁶ The income tax data are consistently lower by about 18 per cent for lawyers and physicians and 13 per cent for dentists. It is unlikely that the whole discrepancy is due to tax evasion. For 1949, the Audit Control Program of the Internal Revenue Service showed an average discrepancy between net profits "reported" and "disclosable by audit" of 4 per cent for lawyers, 6.5 per cent for physicians, and 7.5 per cent for dentists [3, Table 5].⁷ While this is not a full measure of tax evasion, the earnings hidden even from audit would hardly explain the rest of the discrepancy. A more careful and comprehensive enumeration of deductions for tax purposes than for estimat-

⁶ Net earnings of sole proprietorships and partnerships as shown in Schedule C of the income-tax return are available on a per capita basis for 1947 and 1953 and can be estimated with a small margin of error for a few other years for which the number of partners in partnerships is not available.

⁷ The percentages in the text are based on the higher figure, while those in Table 1 of the work just cited are based on the lower "net profits reported."

TABLE 5—PROFESSIONAL EARNINGS OF PHYSICIANS AS MULTIPLES

ing one's income for general information may be part of the explanation; furthermore, the questionnaire surveys, with their low response rates, are believed to have an upward bias, due partly to the reluctance of the less successful professionals to admit, even anonymously, their lack of success, partly to their being less likely to have the secretarial help or leisure needed for answering questionnaires.

In addition to the above derivational differences, there also remain in the data a number of definitional differences. Not only are statistics differently collected in different countries, there are international differences also in the way in which salaries are paid, pension funds set up, and professions defined and separated from neighboring professions. Each of these differences has created problems, none of them serious but many insoluble—at least with the limited resources available to this study.

The data on the earnings of the free professions refer, whenever possible, to independent practitioners only; but in some cases they are over-all averages for the entire profession, which includes independent practitioners and salaried employees. The discrepancies so introduced are probably slight. In the United States, where earnings data are available on both definitions for a part of the period, the earnings of independent professionals fall below in depression and exceed in pros-

perity the average earnings of the entire profession, by a negligible 1 per cent or less for dentists and lawyers, by up to 7 per cent for physicians.

Another problem, only imperfectly resolved, was to find a comparable rank in the civil service. The obvious choice, a cabinet minister, was ruled out by great national differences in the importance of fringe benefits and the difficulties of evaluating them. We adopted the rank immediately beneath him, which minimized these difficulties but at the cost of lesser international comparability. England's permanent under-secretary and Germany's *Staatssekretär* were natural choices: they are the officials immediately below cabinet rank and at the same time also the highest-paid permanent civil servants. In France, the *secrétaire général* was an uneasy compromise; in the other countries, we have chosen the highest-paid officials outside the cabinet, even when they were political appointees.

International comparability remained an imperfectly resolved problem also in the case of professors. Many changes over time and great national differences in the ranks below the full professor forced us to omit them; but even at the professor's rank there are important differences between Europe and America. Professorial chairs are fixed in number and attained only by the select few at most European universities; in America the number of chairs is not limited and the professorship is a rank all faculty members can and most do attain in time. The data compensate for this difference in a crude way, because national averages of professorial earnings in all other countries are set beside U. S. averages that relate only to the 39 best and highest-paying institutions.

A further difficulty only partly resolved stems from the fact that civil servants—and this includes university professors on the Continent—are paid a fixed salary in some countries; in others their basic salary is augmented by rent, cost-of-living, and family allowances. In these latter cases we have taken, whenever possible, the earnings of a married man with two children, living in the capital.

In Europe, university professors usually receive extra pay for examinations. The difficulties of obtaining reliable and complete data on this extra pay forced us to exclude it from our data. Accordingly, the professional earnings of professors in the European countries are somewhat understated in the tables.⁸ In Germany, professors also

⁸ Examination fees may be quite an important source of income in some countries. In Germany, where the rector (president) receives a percentage of all examination fees paid at his university, there used to be a saying (before World War I) at the University of Berlin that a year's tour of duty as rector was worth a villa in Gruenewald, Berlin's most exclusive residential district.

receive *Kollegelder*, fees for each student enrolled in their courses. Earnings from these used to be quite high in the days when all student fees went to the faculty. In the last decades of the last century, a popular professor could earn as much as 100,000 marks (about \$100,000 in today's purchasing power), or 70 times the then-average income of the occupied population. This golden age of the German professor came to an end with legislation of 1898 (and of 1918) which gave him a fixed salary but diverted a part of student fees to the general upkeep of his university. But even today, *Kollegelder*, the professor's share of student fees, amount to DM5.00 (\$1.25) for each semester hour per student enrolled; and, with classes of a thousand or more not uncommon, a popular lecturer, or one whose courses are required, can easily double his basic salary [2].⁹ Unfortunately, data from which to estimate average earnings from these fees are not available. Often the university guarantees a man's minimum proceeds from *Kollegelder*; and we have taken the average of this minimum *Kollegeldgarantie* as our estimate of the average of the actual *Kollegelder*, although this must clearly be an underestimate.¹⁰

The earnings of civil servants and professors include the employee's and exclude the employer's contribution to pension funds;¹¹ and no adjustment was made for the fact that Germany deducts no employee contribution and pays pensions equal to a man's basic salary.

III

The basic data assembled for this study, the time series of net earnings in the different professions and of numbers in the free professions, are shown, separately for each country, in a series of appendix tables not printed here but available on request from the Institute of Business and Economic Research, University of California, Berkeley, California 94720. These tables also contain benchmark data on total and occupied population and national income. The exact definition of each series, the sources of the data, their nature, the way of their derivation, and the assumptions on whose basis some of them had to be estimated are all stated in considerable detail in the footnotes to these tables. This seemed desirable, because the best thing this paper can, and I hope will, accomplish is to draw attention to the existence of these

⁹This book and correspondence with its author were the main source of information about German university professors.

¹⁰The share of *Kollegelder* in average earnings as shown for 1952 and 1956 (in the appendix table) is about 10 per cent.

¹¹However, the government's contribution to physicians' and dentists' pension funds under Britain's National Health Service was included in professional earnings so as to render them comparable to physicians' and dentists' earnings in other countries, where the government does not subsidize their pension plans.

data and to stimulate and facilitate the task of a more ambitious undertaking to collect, render comparable, and publish the kind of data assembled here as a very modest one-man undertaking on an incomplete scale. Estimates made on an exceptionally rough basis or derived from such estimates are within parentheses in both these and all other tables.

The time trends of net professional earnings are shown in this paper as multiples of national income per head of occupation, separately for each occupation in Tables 5 through 9. They are based on the raw data and estimates contained in the unpublished appendix tables. Before looking at these, it is worth considering an international comparison in absolute terms. Tables 3 and 4 show the average net earnings of Europeans, expressed as a percentage of the purchasing-power equivalent of the earnings of their U.S. colleagues, for the year 1955, in a few cases for 1950 (the italicized figures in the tables)—the only years for which purchasing-power equivalents are available. Table 3 is based on European, Table 4 on U.S. expenditure patterns; and if it is true, as is sometimes asserted, that the expenditure pattern of professional people resembles more nearly that of the average European, then Table 3 is the more relevant of the two. Both of them show that it pays to be a high civil servant in England, a university professor in Germany, and a physician in the United States.¹² They also show that the economic

TABLE 6—PROFESSIONAL EARNINGS OF DENTISTS AS MULTIPLES

advantage of the professional over the average man is decidedly greater in England than elsewhere, owing, probably, to the lesser availability in England of academic training and the much smaller proportion of academically trained people.

Another striking fact, shown by these tables and even more by Tables 5 through 9, is the contrast between the limited range within which the free professions', and the very great range over which civil servants', professional earnings vary over time as well as between different countries. A tentative explanation might be that market forces have and always had full scope in determining professional earnings; whereas setting the salaries of high public officials is substantially a political decision.¹³ The very high economic status of high civil

Column (a) refers to the earnings of the Ekspedisjonsjef, until 1930 Norway's highest ranking permanent civil servant. Column (b) shows the relative earnings of the Departementsrod, the new highest rank established in 1930.

¹³ Market forces reassert themselves and force a raising of salary scales when these are set too low; they do not prevent their being set too high.

servants in England, Germany, and France is probably best explained by Tocqueville. In these countries, society seems to accord high civil servants a higher status than they enjoy elsewhere for reasons that probably lie in their political traditions and class structure.

Coming now to the shape of the time series in Tables 5 through 9, they confirm the general impression of a downward trend of professional earnings in relation to the over-all average of per capita national income. All the long series, i.e., all those that go back to before World War I, show a marked downward trend, with those for high civil servants registering the greatest decline. The shorter series show the same downward trend, with the important exception of physicians in the United States. Data on their average professional earnings go back only to 1929 and show a rise. How this series would look if it could be carried back to 1913 I do not know; but it is worth noting that the number of physicians per population in the United States has been declining at least since 1900, while in all the other countries it has been rising. The data on French physicians' earnings also suggest an upward trend; but here the data are too few, the period too short, and the estimates too crude to attach significance to this finding. In general, however, the downward trend of professional incomes is the least pronounced and least well established in the medical profession. Perhaps the great advance in medicine and the resulting greatly increased demand for physicians' services account for this; an important additional factor in the United States probably is the restriction of entry to the profession.

To explain the prevalence of the downward trend, a number of factors were listed at the beginning of this paper. Some of these, such as the increasing supply of education and educated people, would tend generally to mitigate inequalities of income; others, such as the slower than average rise in the productivity of professional people, would explain a fall in the relative earnings of professionals only. This raises the question to what extent the decline in the economic status of the professions is peculiar to them and to what extent it is part of a general trend toward lesser inequalities of income. Could it be that professional people have more or less maintained their relative position on the income scale and that the fall in their relative earnings merely reflects the general compression of the entire income scale? To answer this question, we would need to know much more than we now know. What scanty information is available on income distribution by size is summarized in Table 10 and does suggest a general reduction in inequalities of income over time. It is impossible, however, to attach much significance or even credence to such evidence, because this information is only available for two periods which are too close together and not very comparable, the first period being one of massive unemployment, the second one of full or overfull employment in most of the

THE DOUBLE DEVELOPMENTAL SQUEEZE ON AGRICULTURE

By WYN F. OWEN*

All genuine development reform movements have to come to grips with the reality of poverty in the conditions of economic underdevelopment. Because it is so obvious, it is almost unnecessary to state that in underdeveloped countries the majority of producer-consumers are poor and not rich. However, one of the major implications of this fact does bear restating and further consideration. This is, namely, that in the economically underdeveloped countries any substantial sacrificing of present consumption opportunities, in the interest of higher rates of investment and of corresponding future consumption possibilities, must necessarily fall primarily on the shoulders of the poor. One recent writer has stated this universal law of development, as follows: "In no society have the monied group alone had enough resources to set in motion the really massive savings that underlies the transformation of a static into a dynamic economy . . . the surplus [has] to come from savings imposed on the mass of the people" [59, p. 26].

However, the reality of poverty also comprises a further fact which is rarely accorded the attention it deserves, even though it, also, is quite obvious. This is that the poor of the world predominantly are peasants. The single most important question in development policy in the poorer countries, thereby, turns out to be the way in which the peasants are involved in the accumulation process. Peasants are strategically important not only because of their numbers, but also because they produce one of the most important material inputs associated with the process of capital accumulation, namely, the food and fibers necessary to sustain any labor which is diverted to any other form of economic activity. Beyond this, they also represent the prime immediate source of foreign exchange earnings in many underdeveloped countries. Restated, therefore, the fundamental dual question is: how can peasants be encouraged to produce a cumulative surplus of food and fibers over and above their own consumption, and how can this surplus largely be channeled to investment activity in the nonfarm sector with-

* The author is professor of economics at the University of Colorado and director of the Economics Institute.

out requiring in exchange an equivalent transfer of productive value to the farm sector?¹

In reality, all conditions of economic progress inevitably must incorporate an operational answer to this question, and no genuine development reform movement can avoid it. As has been stated elsewhere "a squeeze on agriculture" seems to be a feature "of all developing societies, whether socialist or capitalist" [5, p. 31].² This is to imply that the difference between the Russian and the U.S. approaches to development lies not in the fact that one exacted or exacts a special contribution from the farmers and the other did, or does, not. Rather the difference lies in the way in which the squeeze has been applied and in the relative efficiency with which the process has operated in each case.

Herein, an attempt is made to examine the differences between these two principal approaches to this essential condition for development. In doing so it will be helpful to differentiate between what might be characterized, respectively, as, first, "The Production Squeeze on Agriculture," and, secondly, "The Expenditure Squeeze on Agriculture." Under the first will be identified intersectoral "requisitioning" of increments to farm production and, under the second, the "requisitioning" of residual farm income for essentially nonfarm-sector, or general social, purposes. The general rule, it will be argued, has been for the impact of this "double squeeze" on agriculture to be positive in both directions in all developing countries. As a result, the cumulative relative saving-investment advantage provided the nonfarm sector has, in all cases, been an important element in the development process.³

In the case of the "farm production squeeze" the respective approaches followed by the leading communist and the noncommunist countries have been quite different, and the first objective will be to

¹ Among other recent statements particularly relevant to this question, those of Kuznets [31], Nicholls [44], and Fei and Ranis [10] deserve special mention.

² Reference to the "squeeze on agriculture" also can be found in much of the classical literature of economic analysis. For example, the phenomenon was referred to by Adam Smith, as follows: "In every country in Europe we find, at least, a hundred people who have acquired great fortunes from small beginnings by trade and manufactures, the industry which properly belongs to towns, for one who has done so by that which properly belongs to the country, the raising of rude produce by the improvement and cultivation of land. Industry, therefore, must be better rewarded, the wages of labor and the profits of stock must evidently be greater in the one situation than in the other" [53, p. 113]. Karl Marx, in a similar vein, stated: "While the country exploits the town politically . . . wherever feudalism has not been broken down by an exceptional development of the towns, the town on the other hand, everywhere and without exception, exploits the land" [39, p. 940].

³ For purposes of this analysis "the farm sector" is defined in the traditional way to include only that part of the process of production of farm commodities that, at any point in time, remains within the boundaries of the farm fence. The word "agriculture" is used interchangeably with "farm sector."

identify and contrast these two models. This is particularly warranted because, while the noncommunist model is quite simple and has had quite spectacular results, it, nonetheless, is not widely understood; leaders of developing countries who might wish to emulate noncommunist procedures have never been provided a very clear-cut prescription of what these really are. After attempting to meet this need, the major components of the "expenditure squeeze on agriculture" in the process of economic growth is examined further. This latter phenomenon, it is shown, assumes the same general form in all countries, whether Marxist or non-Marxist, even though it is subject to different degrees and qualities of exploitation within each of these ideological circumstances.

The final section of the article questions the relative degree of effectiveness with which the product of the double squeeze on agriculture has been put to developmental purposes in the recipient nonfarm sectors of countries falling under the respective influences of the mainstream and the Marxist schools of economic thought. Therein, it is suggested that countries following a noncommunist pattern of development generally have fallen far short of realizing the full potentialities for internal capital formation and economic growth that are inherent in this general pattern. This, if true, has obvious implications for those leaders of the poorer countries who genuinely aspire to higher rates of growth in their countries than those characteristic of most noncommunist countries in the past.

I. The Production Squeeze on Agriculture

A. The Basic Communist or "Marx-Leninist" Model

In relation to the farm output "squeeze on agriculture" the essentials of the communist model are widely understood. However, a brief reiteration of them here will serve as an appropriate background for a contrasting identification of the main noncommunist model. As exemplified by Russian development,⁴ the communist approach has involved a threefold attack on the problem of creating and appropriating an adequate agricultural surplus. First, direct state intervention—through the development, organization, and operation of farming on the basis of state farms, collective farms, and until recently machine tractor stations—has been relied upon as the essential means of promoting increased agricultural production. The primary objective has been the exploitation of anticipated economies of scale and technology, as well as of direct labor supervision and central planning. Secondly,

⁴ Russia is assumed to represent the most orthodox Marxist economy. There have, of course, been important deviations in the ways in which other professing Marxist countries have attempted to create an adequate agricultural surplus.

the first claim on a substantial part of total farm output has been imposed in behalf of the nonagricultural sector through the medium of required deliveries of allocated quotas of agricultural produce to state procurement agencies at nominal prices. This policy also has been supplemented by administered prices for the majority of commodities marketed outside the quotas. Thirdly, a purposive utilization of the acquired agricultural surplus value has been sought in the development-oriented rationing of much of the resulting supply of food and fibers within the urban-industrial sector through the medium of state controlled or sponsored retail stores, service establishments, and consumer cooperatives, and through related wage and price controls [43, Ch. 7] [46] [58] [4].

Disregarding the arbitrary mistreatment of human beings involved in the application of these methods, the Soviet system has proved to be relatively successful in regard to the second and third objectives. Although the working margin, especially in recent years, has been uncomfortably narrow, at least to date, a substantial and a sufficiently regular supply of farm products has been extracted from Russian agriculture to support an expanding urban-industrial community and an extremely impressive industrial growth rate [47, p. 289]. The peasant, in these circumstances, as the residual claimant on agricultural output, has been a primary risk bearer and primary involuntary saver. In regard to the first objective, however, namely, the stimulation of increasing productivity in agriculture, the results have been much less impressive. Agricultural production in Russia fell substantially following the revolution, and had the communist leaders not been able to draw upon the previous export surplus of farm products to meet domestic needs, this decided agricultural developmental failure would have had much more serious implications. In spite of the impact of several "crash programs" in agriculture in recent years, the record in this sector still remains an obvious cause for embarrassment and internal conflict among the Russian communist leadership [18] [52]. The general stalemate, and in some instances, such as in Poland and Yugoslavia, the actual reversal of collectivization plans for agriculture in communist-dominated countries of Eastern Europe provide further evidence of the general communist dilemma with regard to the agricultural sector. Clearly, in China, where population pressure on the land and an initial food deficiency leaves an even smaller margin for error in the programming of agricultural development, the question of whether or not to follow the Russian prescription in this area is one that the indigenous communist leaders also can avoid raising in that country only in blind ideological defiance of experience and of their own interests.

B. *The Contrasting Major Noncommunist or "Mill-Marshallian" Model*

The analogous approach, which in varying degrees of perfection has been common to the development record of all of the major noncommunist countries, appropriately might be referred to as the "Mill-Marshallian" model, since the major insights upon which it stands were apparent in their essentials to these contemporaries of Marx and Lenin. The model has two primary features. The first of these is the organization of agricultural production activities in family *operational* units;^a that is, in the form of the individual proprietorship type of economic organization, in contrast to those other "more advanced" forms of organization—in particular the private and public corporation or cooperative—which have assumed such an important position in the nonfarm sectors of economically advanced countries. The model requires that this type of atomistic organization of the farm sector—comprising a large number of relatively small independent production units related to one another in a manner closely approximating the economists' conception of "pure competition"—persist, even though the nonfarm sector acquires increasingly generalized degrees of concentration and of monopolistic tendencies.

The second essential feature of the model is that the farm sector, thus organized in its internal nature, also be oriented substantially, and increasingly so, to production for the purpose of acquisition through exchange of nonfarm-produced factors, commodities and services, in contrast to the traditional orientation of a subsistence economy, namely, production for the direct satisfaction of the producer's economic purposes. The major implications of each of these two essential features of the Mill-Marshallian model—or of what equally well can be referred to as "a market-oriented, family farming system"—will be discussed in turn in some further detail. Illustrative materials will be drawn mainly from the record of the United States since this country, undoubtedly, has achieved the highest level of development of this particular model. However, in a more comprehensive treatment corresponding examples could be cited from the records of such countries as Great Britain, Canada, Australia, Japan, most Western European countries, and many others.

Economies of Scale. In the industrial-urban sector historical evidence and economic analysis overwhelmingly support the assumption

^a It is not essential, although in many circumstances and stages of development it may be desirable, for the operational unit also to be owned by the operator. It also is emphasized that it is not meant to imply that the model necessarily should be assumed to be relevant to the process of pre-farming land development as well as to that of farming itself.

that economic progress and relatively large-scale production, as exemplified by the factory system, go hand in hand. Yet, whether we consider the case of the United States or of any of the other well-developed countries of the noncommunist world, the fundamental and common reality in the basic organization of agricultural production is the family farm. This fact, together with the impressive productivity record of the agricultural sectors of most of these countries, has always presented somewhat of a contradiction in the context of conventional Western economic thought. That the contradiction troubled Alfred Marshall is very apparent in his *footnote* expression of the hope that someday someone might discover the secret of the factory farm.⁶ However, Marshall was realistic enough to recognize that the factory system could not easily be applied to agriculture, and in general he seemed to conclude it best to consider agriculture as "a case apart." It is probably fair to say that most economists have since attempted to resolve his dilemma by avoiding it. That is, the main body of economic doctrine in the West emerged in a form that most properly should be referred to as "urban-industrial economics." "Rural-agricultural economics" was left to develop, separately and belatedly, a largely independent and peripheral academic career of its own.

In this setting it followed that the main body of economic thought had only a minor influence on the development and retention of the type of production organization in agriculture which typically became established in most of the more advanced noncommunist countries. The family farm was more a product of physical and political realities⁷ than a response to any particular economic doctrine, even though it is true that the implied benefits of classical competition have often been

* "The experiment of working farms on a very large scale is difficult and expensive, because it requires farm buildings and means of communication specially adapted to it; and it may have to overcome a good deal of resistance from custom and sentiment not altogether of an unhealthy kind. The risk also would be great; for in such cases those who pioneer often fail, though their route when well trodden may be found to be easiest and best.

"Our knowledge on many disputed points would be much increased and valuable guidance gained for the future if some private persons, or joint-stock companies, or cooperative associations, would make a few careful experiments of what have been called 'Factory farms' " [35, p. 652].

⁷ Undoubtedly the primary influences were of a geographical and demographical nature with such political philosophies as the Jeffersonian concept of rural democracy playing complementary roles. Only in these terms can the essentially common patterns of settlement on the frontiers of the United States, Canada, New Zealand, Australia, South Africa, and of several other parts of the world be reconciled one with the other. As another writer [35, p. 360] has put it, "it was largely a happy circumstance that the technical aspects of agriculture coincided with the economic, social and political framework which he [Jefferson] envisaged."

drawn upon for subsequent arguments in its defense. On the other hand, Marxist-Leninist economics and the attempted method of agricultural organization in professing communist countries have had very close connections. Lenin confidently associated himself with Kautsky's conclusion that "the superiority of large-scale farming over small farming even in regard to cooperative organization is fully confirmed" [34, p. 162]. Thereby the collectives and, even more so, the state farms of the USSR became logical, practical expressions of the basic Marxian doctrine.

In marked contrast to Marx and Lenin, John Stuart Mill, after very careful deliberation, earlier had concluded that "the superiority of the large scale system in agriculture is by no means as clearly established as in manufacturing" [41, p. 144]. Likewise, Alfred Marshall, though ever hoping for evidence to the contrary, felt that the only honest conclusion to be drawn was that "the economies of production on a large scale are not quite similar in the two cases," and that agriculture, "even under the English system, cannot move fast in the direction of the methods of manufacturing" [38, p. 651].

Quite clearly Mill's position, as the classical school's champion of the family farm, was largely determined by his insight into the implications of the second limitation to the division of labor, namely, the nature of employment.⁸ The key phrase in Mill's statement is the assertion that the different operations of agricultural production "cannot possibly be simultaneous." Rather, they must be performed sequentially.⁹ In other words, it is impossible to sow the seed and gather the grain at the same time, while it is possible for the different components of an automobile to be manufactured simultaneously with one another and with the assembly of the final product. Add to this the closely related spatial limitations to the increasing scale of operations in agriculture, explained, among others, by Marshall [38, pp. 290,

⁸The first limitation, of course, was the extent of the market. With regard to the nature of employment in agriculture, Mill wrote: "Agriculture . . . is not susceptible of so great a division of occupations as many branches of manufactures, because its different operations cannot possibly be simultaneous. One man cannot be always ploughing, another sowing, and another reaping. A workman who only practised one agricultural operation would be idle eleven months of the year. The same person may perform them all in succession, and have, in most climates, a considerable amount of unoccupied time. To execute a great agricultural improvement, it is often necessary that many labourers should work together; but in general, except the few whose business is superintendence, they all work in the same manner. A canal or a railway embankment cannot be made without a combination of many labourers; but they are all excavators, except the engineers and a few clerks" [41, pp. 131-32].

⁹This insight of Mill has been developed in an important recent article by John M. Brewster [6].

651]—the inevitability that increasing size of farms will result in the need to send the workmen “over the hill” and beyond the sight and supervision of the operator—and the essential point becomes quite obvious: the factory, meaning that type of large-scale enterprise which is characterized by a large payroll, is, except under quite special conditions,¹⁰ incompatible with the nature of the task of agricultural production.

To seek to impose the factory upon agriculture is, therefore, to defy some rather convincing facts of life. Western countries in general have not deliberately tried to do so, and this quite clearly has been to their advantage in economic development. The continuously evolving family farming system of agriculture in the United States not only remains unsurpassed in productive efficiency by any differently organized agricultural industry anywhere else in the world, but its record also compares very favorably, and increasingly so, with that of the non-farm economy. For example, one study reports an average annual rate of increase in total factor productivity in the United States between 1889 and 1957 (a 68-year period) of 1.3 per cent in the farm sector compared with 1.8 per cent in the nonfarm sector, but with the rate of increase in the farm sector during the final decades of 1937-48 and 1948-57—namely, 2.7 per cent and 3.7 per cent, respectively—considerably exceeding the 2.0 per cent rate in both decades in the nonfarm sector [28, p. 1560].

It is interesting to note, further, that in the United States, where the possibilities of establishing factory farming are as open to experimental test as any other form of agricultural economic organization, there really has not yet emerged convincing evidence in support of the contention recently voiced by Higbee [25, pp. 77-94] to the effect that the factory farm, or *hacienda*, is in process of generally displacing the family farm at the operational level. Following the English pattern there is likely to develop in the United States an increasing concentration in farm land and farm capital ownership and control, embracing many farm operational units in a single land or capital estate, but among farm operational units, or farm firms, large-scale family farming in the United States remains fully competitive in all of the major lines of agricultural production. Thus according to one recent study there was, between 1949 and 1959, an actual decline of 24 per cent in

¹⁰ In practice the most common “special conditions” have been those incorporating a large supply of unskilled and subservient labor—such as the plantation South and migrant labor regions of the United States and the *latifundia* of South America—and those, normally atypical, types of farming which involve a high spatial concentration of labor-intensive productive activity, such as specialized fruit and vegetable farming, irrigated agriculture, and specialized livestock feeding.

the numbers of larger-than-family farms¹¹ marketing more than \$10,000 worth of farm commodities, while at the same time family farms in the same category increased in number by 104 per cent [29, p. 630].¹²

Market Orientation. It can be concluded, therefore, that it is still much more realistic for developing countries to pursue the potentialities for technological advance inherent in the old-fashioned family farming structure than the imaginary economies of the larger-than-family or "factory" farms. The development record of Japan clearly attests to this truth [21, p. 767]. However, and equally important, is the second essential component of the Mill-Marshallian model, namely, a meaningful degree of market orientation in the economic activities of the family farmer. That is, the farmer's standard of living and his production activities must be significantly dependent upon goods and services and productive resources which he acquires through exchange rather than as a direct result of his own productive efforts.¹³

One of the primary functions of such market orientation in the operation of the model is to provide for an automatic realization of the productive potentialities which are inherent in any given state of the agricultural arts, and this within whatever limits are imposed on the latter by the demographically practicable pattern of family-farm sizes. The mechanism whereby, given a market-oriented family farming structure in the agricultural sector, technological progress and increasing productivity in farming are rendered essentially automatic has been well described in almost all elementary textbooks of economics. The commercial family farmer under the dynamics of a traditional competitive environment represents an individual Ricardian capitalist *par excellence*, forever reaching forward for new technologies in order to keep from losing position on that reverse escalator of declining per unit average real costs, which is a characteristic of any industry that is making a positive contribution to general economic progress. In contrast to the related types of opportunities which are open to many of his principal counterparts in the nonfarm economy, no farmer-manager, of his own volition, can exclude or retard his competitors—other farmers—also

¹¹ That is, farms on which hired labor exceeds the labor contributed by the operating family. Since the average farm family in the United States contributes the equivalent of one and one-half man-year units of labor, this implies that on the average, family farms, by this definition, normally would not provide employment for more than a total of three full-time equivalent units of labor including that of the operating family.

¹² For further support of the general position that the efficient family farm is not seriously threatened by the factory farm, see H. L. Stewart [54] and M. Harris [19].

¹³ The trading partners of such an interdependent family farmer necessarily will include other farmers as well as nonfarm-sector producers, although it is the latter with which this article is primarily concerned.

from adopting and fully exploiting at will any new methods or technologies that arise in the industry, and quite irrespective of the source of the innovation. The best he can hope to achieve is to keep in the lead. Should he become a victim of, rather than a victor over, the circumstances, he more likely than not will be faced with little else than the equally unattractive economic alternatives of descending into the lost world of noncommercial or low-income "farmers," or of drifting into the ranks of their city cousins—the urban unemployables and slum dwellers.

In reality, in most countries in which the Mill-Marshallian model has played an important role in the process of development, only a very imperfect application of the model has really been achieved. Thus, the common characteristic of family farms in most countries is that too many of them tend to be too small to provide for a full realization of their productive potentialities,¹⁴ and in far too many instances established family farming systems have remained substantially, if not primarily, oriented to subsistence economics, rather than becoming an integral part of a national exchange economy. The record of the rural economy of France following the Revolution provides an interesting case in point [40]. Nevertheless, while its limits have nowhere been reached, it is apparent that the model has been quite highly developed in several countries and especially in the United States. Thus, in 1959, 94 per cent of all commercial farms¹⁵ in the United States were family farms according to the preceding definition. Furthermore, farm families by 1960 had become market-oriented to the extent that only 9.5 per cent of their earnings from farm sources comprised directly consumed farm products, including the rental value of farm dwellings, (cf. 1910-14, 23.7 per cent), and 71 per cent of the inputs of commercial agriculture by market value were supplied from off-farm sources (cf. 1919, 53 per cent). Mobility of resources in response to changing market conditions in the United States also had become sufficient in the two decades ending 1960 to accommodate a decline in the farm labor force by 39 per cent, and in the total numbers of farms by 25 per cent [69, pp. 40, 44, 46]. Correspondingly, there was an increase in the average acreage of farms by 65 per cent, and due to a greatly expanded commitment of capital resources,¹⁶ an even

¹⁴ Thus, even in the United States, informed observers claim that (in 1959) family farms of adequate size represent only about 18 per cent of all farms and only about 28 per cent of all commercial farms [19, p. 540].

¹⁵ That is, farms on which the operator worked off the farm for less than 100 days a year, and on which income from farm sources provided more than one-half of the total income of the farm household.

¹⁶ Between 1940 and 1960 total farm usage of machinery and motor vehicles increased by 138 per cent; farm real estate (in spite of a decline in cultivated land) by 13.6 per cent, and total farm livestock by 3.2 per cent [65, p. 3].

greater increase in the total sizes of family farms as business concerns.¹⁷

"Priming the Pump." The tendency for an atomistic market-oriented agriculture automatically to devour compatible new technologies can be and has been widely exploited in many countries through the adoption of policies designed to accelerate the process. The speed of this "agricultural treadmill" [9, pp. 85-107], which a family farming system inherits along with market opportunity, quite obviously tends mainly to be conditioned by the degree to which knowledge and access to new methods and techniques are generally available to farmers. Thus, the Mill-Marshallian model provides a framework within which increased agricultural production, on a cumulative basis, can be rendered essentially automatic and almost a direct function of public investment in agricultural research and rural education and of the adequacy of complementary rural financial institutions and farmer's financial reserves. It is to be noted in this last connection that, insofar as farm investments are largely self-financed, the subsidization of farm incomes through price support or other methods can be viewed as an alternative approach to the same objective as that served by the improvement of rural financial institutions. That is, farm income supports can represent an important element in the pump-priming process.

The record of the United States may also be cited as evidence of the potentialities inherent in such pump-priming devices, although it should be noted that the United States, in this respect also, has by no means fully exploited the possibilities. In spite of the natural obstacles to research and innovation which are presented by the structure of agriculture—especially its geographical spread and the fragmentation of the managerial and investment functions—and in spite of the related benefits often cited in behalf of large-scale production in industry [12, Ch. 2], there is convincing evidence that in the United States over the period 1909-49 "technical change in agriculture was twice as rapid as in manufacturing" [33, p. 950].

The "Pay-Off." However, there is still a further important question to examine. This concerns the degree to which this model also provides that at least a substantial part of the realized increments in agricultur-

¹⁷ In 1960 the value of total physical farm assets in the United States amounted to \$34,648 per farm, which in constant dollar amounts represented an increase of 82 per cent over the corresponding figures for 1940 [65, p. 19]. As an integral part of the process of market orientation and economic interdependence, but still within the context of a family farming system, increasing economies of scale thus have also played a substantial role in the spectacular rate of growth which has characterized U.S. agriculture in recent times. During the period 1940-60 total farm-sector output in the United States increased by approximately 50 per cent [16, p. 341]—and, of this, Griliches estimated that about 40 per cent was "due to the expansion that occurred in the scale of the average farm enterprise" [16, p. 346].

al productivity is diverted to the potential support of economic development in the nonfarm sector in contrast to its being dissipated in immediate farm-sector consumption activities. Compulsory deliveries of food under the Marx-Leninist approach clearly represent a direct tax on the farm sector in behalf of the nonfarm sector. It is not so obvious that a market-oriented family farming system also provides an extremely efficient means to such intersectoral taxation. The form of the tax and its method of collection are quite different than under the Marx-Leninist model, but that it exists cannot be denied.¹⁸ As already stated, its existence constitutes a developmental imperative.

Simply stated, the gain to the nonfarm sector, under the Mill-Marshallian model, takes the form of an intersectoral profit on technological progress. It represents a residual surplus accruing to the nonfarm sector on the rewards of economic development in the farm sector, over and above any equivalent sharing by the farm sector in the corresponding gains from technological progress generated in the rest of the economy.¹⁹ In place of the delivery of a quota of farm production to the "peoples' government" under the political compulsion of communism, the market-oriented, family farming system delivers to the nonfarm sector, under the compulsion of the competitive market, progressively increasing supplies of food at progressively lower costs. This is to say that, under these circumstances, the benefits of technological progress in agriculture are automatically and rapidly passed on to nonfarm processors and consumers as the cumulative impact of innovating farmers increases the total market supply of the farm commodities in question and produces a corresponding fall in the average market price [60, pp. 467-86]. This process in turn rapidly erodes away the ephemeral profits of that select minority of farmers who constitute the vanguard in respect of any particular changing technological circumstance in the farm sector.

What is so unique about this? Is it not true that the same kind of sequence of events also applies to the process of technological advance in the nonfarm sector? That is, does not the adoption of innovations in

¹⁸ This general proposition has also been presented by B. H. Johnston [27] and by P. M. Raup [49]. To quote Raup: "The similarities between the effects of the ration system and those of the pioneer development phase in North America should not be overlooked. . . . However dissimilar the political and social climates in the two areas may be, the economic process has been roughly comparable. . . . Whatever the motivational structure, whatever the formal name attaching to the extraction system, the consequence has been the same: a tax, in the broad sense of the term, has been laid on agriculture for the provision of capital needed in industrial growth" [49, pp. 316, 317].

¹⁹ This proposition plays a central role in a recent analysis of current United States agricultural policy by E. O. Heady [22] who states that: "The distribution of gains and losses of technological and economic progress provides the main basis for the policy problems of commercial agriculture" [22, p. 10].

the nonfarm sector likewise tend to be translated into a gain to the consumer in the form of lower real prices and, furthermore, does not the farmer as a consumer in this way get repaid for his contribution to total economic growth? In principle the answer to these questions must, of course, be "yes." However, it is also true that, when viewed in a dynamic sense, the relative total impact of the same general process on the two sectors can be quite different if there are differing overall time lags between the adoption of innovations by the component-producing groups and the realization of cheaper commodities and services by the consumer. The presence of significant degrees of natural and acquired monopoly power in the hands of a large proportion of nonfarm producers and of associated industry-wide positive profit rates means none other than that these producers do have the power in varying degrees to delay the transfer of the benefits of technological progress to the consumer; in other words, they have the power consciously to lay claim for a somewhat longer period of time to the profits which everywhere accrue to the innovator or first adopter. In the farm sector, on the other hand, competitive conditions insure that the corresponding time lag and the cumulative aggregate rate of profit accruing to the farm sector on its own innovations is kept to the absolute minimum.²⁰

In the dynamics of growth this phenomenon gives the nonfarm sector, under the conditions of the Mill-Marshallian model, a perpetual advantage in respect of its claim on the total income stream vis-à-vis the farm sector, which really amounts to a dynamic form of intersectoral taxation expertly administered by the "invisible hand." It deserves to be noted in this general connection that Adam Smith's reference to the squeeze on agriculture was conditioned by his belief that there tended to exist a different and higher plateau of prices in the towns than in the country and that this placed the latter at a substantial and cumulative relative disadvantage in a market economy. He viewed the phenomenon itself to be a natural outcome of the inherent tendency toward combination under urban conditions and the inherent opposite tendency under rural conditions.²¹

²⁰ "The first few farmers who adopt innovations do realize a positive pay-off. The masses who follow in adopting innovations and augmenting the supply function, however, are the ones who make the greatest absolute contribution to lessening the real price of food and to freeing resources from agriculture. Yet these producers are promised negative pay-offs or costs from the contribution, because their incomes are reduced from the process under inelastic demand" [22, p. 10]. In the nonfarm sector the "first few" invariably represent a sizable majority rather than the minority.

²¹ In Adam Smith's words: "The inhabitants of a town, being collected together into one place, can easily combine . . . it was the manifest interest of every particular class of them to prevent the market from being over-stocked, as they commonly express it, with their own particular species of industry; which is in reality to keep it always under-

How Much Benefit? Having recognized the phenomenon, the logical question to ask next is: What is the magnitude of this *dynamic intersectoral concealed and cumulative tax* on agriculture in countries, such as the United States, where the Mill-Marshallian model applies? Due to the nature of the phenomenon this question does not lend itself to precise answer. However, it is reasonable to assume that a part of the pronounced income differential which exists in most countries between the farm and nonfarm populations,²² and especially the failure of this differential to close over time, is subject to explanation in these terms. It also is apparent on the basis of several indicators that, even in a country as highly developed as the United States, this intersectoral tax still represents a very significant flow of funds.

To mention one such indicator, it is instructive to consider the implication of placing the farm sector on a more nearly equivalent basis to the nonfarm sector with respect to aggregate industry profit balances or, in other words, to aggregate rewards for innovation and risk-taking. As already noted, a negative aggregate profit balance, without doubt, is the "normal" condition in the farm sector. By contrast, profit margins, after taxes, of all manufacturing in the United States throughout the 1950's amounted to between 4 and 5 per cent of sales [63]. Even more impressive, the aggregate profits of the larger nonfarm corporate sector, also after taxes, ranged from \$16.8 billion to \$24.5 billion per annum over the decade of the 1950's, with the average (based on five years) increasing from an annual rate of \$16.5 billion in 1950 to \$22.3 billion in 1960 [64, p. 281]. Had the farm sector experienced a supplementary return proportional to the profit rates of these two components of the nonfarm sector, this additional return would have increased the net farm income in 1960 by between \$1½ and \$2 billion.

stocked. Each class was eager to establish regulations proper for this purpose, and, provided it was allowed to do so, was willing to consent that every other class should do the same. In consequence of such regulations, indeed, each class was obliged to buy the goods they had occasion for from every other within the town, somewhat dearer than they otherwise might have done. But in recompense, they were enabled to sell their own just as much dearer, so that so far it was as broad as long, as they say; and in the dealings of the different classes within the town with one another none of them were losers by these regulations. But in their dealings with the country they were all great gainers; and in these latter dealings consists the whole trade which supports and enriches every town. . . . The industry of the town becomes more, and that of the country less advantageous" [53, pp. 108-17].

²²Clark [8] and Bellerby [2] provide relevant comparative data on this point. For the United States, it might be noted that, based on disposable income figures, it would have taken \$14,384 million in 1950, and even after a reduction of 35 per cent in the farm population, \$13,182 million—or 3.7 per cent of the total national disposable personal income—in 1960, to raise the average level of income of the farm population to that of the nonfarm population [69, pp. 40, 41].

This figure would appear to be quite conservative, when viewed against the rates of return which have been found to accrue to expenditures on agricultural research and extension. Most related studies indicate an annual rate of return of about 100 per cent [51, pp. 120-22] [15, p. 428] [22, pp. 600-601] [57], which rate, according to one study [57], applies even if expenditures on price support, surplus disposal, and rural education and improvement are all included in the total outlays.²³ For purposes of this present analysis it is necessary to carry these estimates one important step further and recognize that, under the operation of the Mill-Marshallian model, the impressive returns cited are "paid off" in the form of lower prices for farm products. Thus they accrue primarily to nonfarm intermediaries and consumers and represent a handsome profit to the latter on any funds they contribute to the pump-priming operation. It would appear that in recent years in the United States, the nonfarm sector probably has been earning about two dollars for every dollar it has contributed to such expenditures, as well as receiving the major share of the corresponding benefits which have accrued to outlays for similar purposes originating in the farm sector itself. It should be obvious to development planners in all countries that, once a working version of the Mill-Marshallian model has been incorporated into an economic system, these types of outlays represent extremely strategic points for the injection of development-oriented public expenditures.

II. *The Expenditure Squeeze on Agriculture*

The foregoing argument points to the conclusion that a market-oriented, family farming system represents a very promising initial policy objective for leaders of less developed countries; an objective which once achieved will enable them to drive their predominantly agrarian economies toward higher rates of growth without resorting to uncertain and unsavory totalitarian alternatives.²⁴ In respect of over-all

²³ Tweeten and Tyner [57, p. 1078] indicate that the total annual outlay on these items in the United States, currently amounts to approximately \$8 billion, including \$0.8 billion for public and private research and extension work and \$3.5 billion for price support and surplus disposal programs.

²⁴ The several problems, likely to be associated with the establishment of an operational version of the Mill-Marshallian model in developing countries, require separate treatment. It is suggested, however, that in most circumstances these problems are of a second order to the initial task of having the establishment of this model included among the objectives of developmental planning. The latter must wait upon the emergence of a wider understanding of the model and of its potentialities among the leaders of developing countries. Once the objective of the Mill-Marshallian model becomes a conscious component of developmental planning such questions as land tenure, farm size, agricultural research and education, credit and price stabilization programs, and planned investment, both in agricultural and in the farm factor supply and farm product processing sectors, can be approached with a new sense of their relevance to the over-all process of economic growth.

growth policy it provides an important part of the answer to the dilemma which was posed at the outset²⁵ by ensuring that the farm sector not only will generate a high internal rate of growth, but also for internal structural reasons will be unable to lay claim to more than a very limited share of its incremental contribution to the over-all rate of growth.

However, what has been discussed thus far by no means represents the complete story. No doubt, more important from the farm income point of view are two further considerations which help to clarify the oversimplicity of the historically popular argument that low farm income can be corrected through a more rapid out-migration of labor from the farm sector.²⁶ These considerations are, first, the perpetual loss of capital from the farm sector associated with the historical phenomenon of off-farm migration and, secondly, the unavoidable inheritance by the farm sector of the responsibility to compensate labor resources which are rendered redundant in its contribution to over-all economic development, but which fail to find employment elsewhere. These considerations will be discussed briefly.

A. "Emigrant Capital"

One of the characteristic features of the development process in these countries is the progressive saving of labor resources in farming through increasing labor productivity and the reciprocal utilization of this labor in industrial production and service activities [8]. The so-called "drift to the city" of farm population goes hand in hand with general economic development. What is not so widely recognized is the fact that the costs of rearing and, in countries like the United States, the costs of providing a basic education to this stream of migrant labor are very considerable. Insofar as this labor is, in this sense, essentially "costless" to the nonfarm sector, it can represent a sizable continuous outflow of "capital" from the farm sector.²⁷

The earliest known study made of this phenomenon, relating to 1900 data in Tennessee, indicated that the associated annual rate of disinvestment from the farm sector in respect of Tennessee agriculture

²⁵ Simon Kuznets has expressed this dilemma in these words: "one of the crucial problems of modern economic growth is how to extract from the product of agriculture a surplus for the financing of capital formation necessary for economic growth without at the same time blighting the growth of agriculture, under conditions where no *quid pro quo* for such surplus is available" [31, p. 70].

²⁶ This case was restated quite blatantly in a recent publication of the Committee on Economic Development [61].

²⁷ By contrast the inflow of capital resources to the farm economy to support technological progress therein is fully—some might argue more than fully—paid for by the farm economy.

amounted to a total of at least \$139 million, or to at least \$3,300 per migrant, and to at least \$600 per year for every farm in that state [37, p. 368]. If the same estimate of the nonrecoverable costs to the farm economy of rearing and educating emigrating labor resources is extrapolated, the corresponding annual disinvestment rate for the United States farm economy as a whole, during the five years ending 1951,²⁸ comes to almost \$3,000 million and to over \$550 per year for every farm in the nation.²⁹ This was at a time when the average net income per farm, from both farm and nonfarm sources, amounted to \$3,490, and when only \$44 of this constituted direct government payments [66, pp. 40-41].³⁰

These estimates, however, were extremely conservative even for Tennessee. They were based on the costs of rearing potential migrants to the age of only 15 years, and this in farm families having disposable cash incomes of less than \$1,250. In the same study comparable estimates are provided for Tennessee farm families with disposable net cash incomes of over \$2,200, which no doubt were more representative of the U.S. farmers as a whole. Based on this group the disinvestment rate associated with off-farm migration in 1949 was about \$4,425 million for the total U.S. farm sector and about \$820 per year for every farm. However, this estimate assumed total direct and indirect schooling costs of only \$260 per migrant, and an average of only eight years of schooling. Actually, in the year of the study, the cumulative investments in school training to the age of 15 years for the United States averaged \$939 per student [42, p. 50], and average current expenditures, excluding interest, in public day schools were running at \$130 per pupil in Tennessee and at \$209 per pupil throughout the country [72, p. 28, 29]. Furthermore, the median years of schooling completed by all U.S. farmers between the ages of 22 and 75 years of age was 8.3 years as of 1950 [13, p. 53] [17, p. 23] and for the farm emigrant population undoubtedly it was somewhat higher than this.³¹

²⁸ The statistical record shows an extremely low out-migration of farm labor in 1949 (371,000 compared with the representative average annual net rate of 890,400 for the 10 years ended 1949, and 838,600 for the 10 years ending in 1959). The average for the five years centering on 1949 was 904,000 [71, p. 613].

²⁹ That is, for every piece of land that was cultivated independently and which produced \$150 of agricultural products or which comprised more than 3 acres (definition of a farm in the 1950 Census of Agriculture). There were 5,382,000 such farms in the United States in 1950.

³⁰ The average net income per farm from farming alone in Tennessee in 1949 was \$1,427 and in the United States as a whole it was 63 per cent higher, or \$2,401 [68, pp. 17, 25]. The latter figure was further supplemented by \$966 per farm (or 40 per cent) from off-farm work [66, p. 34].

³¹ One study cites the median years of school completed by farm-urban migrants in 1940 as 8.5 years [26, p. 407].

It is quite realistic to assume, therefore, that in the early 1950's the continuing drain on the total U.S. farm economy represented by its non-recoverable expenditures on the rearing and education of the off-farm migrant stream, probably was at least \$5 billion per year and in excess both of \$5,000 per migrant³² and \$1,000 per farm per year. Clearly the farm subsidy programs of the various more highly developed countries, though invariably a focus of political controversy, may be expected normally to fall far short of compensating the farm sector for this invidious capital drain which the process of development imposes upon it.

More precise estimates of the capital loss to agriculture associated with off-farm migration are needed.³³ Such estimates should also take account of the qualitative losses which result from the high degree of selectivity which is associated with the market for redundant farm labor, as well as purely quantitative data. It is well established that the farm-nonfarm migrant stream tends to represent a younger working population than that which remains on the farm [26, p. 407] [20, p. 382]. Thus, it comprises a higher proportion of earners relative to dependents; and, although the relationship in this respect has not been so clearly demonstrated, also important is any tendency for the migrant stream to carry with it the more highly trained and experienced [1, p. 82] [20, pp. 382, 383] [36, pp. 430-31], and perhaps also those

³² A more recent study claims that the *net* cost of rearing and educating farm children to the age of 18 in 1954 averaged as much as \$12,927 [56], which is about 87 per cent higher than the Long and Dornier estimate, when the latter is adjusted to take account of price changes and different sample age brackets. This 1954 estimate was an average for both sexes. The figure given is net of earnings of farm children prior to age 18. It excludes any monetary value of the household labor of mothers, losses due to the death of children, "interest charges" on the maintenance costs of the children and public costs associated with health and recreation.

³³ Simon Kuznets has demonstrated one approach to this task. He has estimated that if a hypothetical underdeveloped economy in which the share of farming in the national labor force was 75 per cent and its share in the net national product 60 per cent, were to develop over a decade at such a rate as to result in a reduction in the agricultural share of the labor force to 70 per cent, the transfer of embodied capital in the out-migration of farm labor would represent, in the first year of the decade: 10.1 per cent of the agricultural-sector income, 25.0 per cent of the nonagricultural-sector income, and 6 per cent of the net national product. In presenting these figures he stated that "it would have been easier, without violating the rules of plausibility, to raise this percentage than to lower it." Even so, 6 per cent of the NNP almost equals the total rate of new savings that might reasonably be expected to apply in such an economy. Kuznets acknowledges, of course, that the percentage of the nonfarm-sector income represented by imported embodied capital would tend to fall as the process of development proceeds. However, he also rightly emphasizes that the relative burden of the cost of rearing and educating emigrant labor on the diminishing farm sector also increases as the process of development proceeds [31, p. 74].

members of the rural community with the higher entrepreneurial capacities.³⁴ That there tends to be a continuing erosion of talent from the farm labor force, over and above numerical estimates of the migration rate, cannot be seriously doubted.

It should be re-emphasized that the phenomenon discussed above is not peculiar to countries whose agricultural sector is organized along the lines of the Mill-Marshallian model. Indeed it is quite apparent that in all developing circumstances a substantial fraction of the basic costs of rearing and educating that part of the nonfarm labor supply that originates in the farm sector will be borne by the latter. It is also apparent, however, that to the extent that public educational and health facilities are financed from general revenue rather than from local revenue sources, the burden upon the farm sector will be mitigated in some degree, and its contribution to the over-all process of capital accumulation will be correspondingly reduced. It might be noted in this connection that, inherent in the U.S. historical emphasis on local responsibility and autonomy in basic public education, has been the tendency to maximize the farm-sector share of the cost of its long-standing policy of compulsory basic education for all citizens. Thus, in 1950, 56.3 per cent of the costs of public elementary and secondary education in the United States was financed by local or county government bodies, with only 39.8 per cent and 2.9 per cent, respectively, being derived from state and federal sources [72, p. 28].

This suggests that the U.S. type of educational system has an additional important advantage for developing countries over and above the political and social advantages of local autonomy which are most commonly cited in its support. It also is of considerable significance that this type of educational system is particularly compatible with a family farming system, and thereby with the Mill-Marshallian model.

B. Farm-Financed Social Welfare

Last, but by no means least, there remains to be discussed a second subsequent "nonfarm" claim against that limited part of the total income stream which passes into the hands of the farm population. This is the claim to maintenance at farm-sector expense of any labor that is rendered redundant by the development process in that sector until

³⁴ "This probability and its implications for the farm sector impressed Alfred Marshall, viz., "there is . . . very little inducement for really able men to enter the business of farming; the best enterprise and ability of the country generally avoid agriculture and go to trades in which there is room for a man of first-rate ability to do nothing but high-class work, to do a great deal of it, and therefore to get high earnings of management."

such time as this labor actually realizes an alternative employment opportunity in the nonfarm sector.³⁵

Traditionally the major emphasis in economic analysis has been in the direction of implying that the responsibility for the existence of "surplus labor" in agriculture falls on the surplus labor itself. In its most extreme form, this position advances the argument that the farm problem is created by artificial farm-income support which upsets the intersectoral balance between marginal productivity and marginal return and thereby inhibits the flow of labor out of agriculture. However, in recent years there has been increasing support for the more realistic position, especially under conditions of substantial nonfarm unemployment, that the comparative marginal productivity of redundant farm labor *in the nonfarm sector* tends to be zero, or less than zero,³⁶ and will tend to remain so until such time as the necessary realizable job opportunities become available to it in that sector [55, Ch. 6] [45] [25, p. 105]. This view implies that the existence of surplus farm labor is more a nonfarm or general social responsibility than the primary responsibility of the low-income farm population itself.³⁷

But notwithstanding the emergence of such a view, and of certain policies consistent with it, one cannot help but be struck by the "heads-I-win, tails-you-lose" type of circumstance in which the farm sector is placed in the development context. If realizable employment opportunities are created in the nonfarm sector through an adequate development program therein, then the nonfarm sector is able to tap a reservoir of mature labor resources without incurring the "rearing costs" and the basic training costs of this labor, and in most cases also the costs of its relocation. If, on the other hand, the nonfarm sector should fail to make available the needed job opportunities, then this potential labor supply can be left indefinitely where it is at the expense of the farm sector. Redundant farm labor, especially in the context of a family farming system, tends to take the form of *involuntary underemployment* rather than the form of its more politically explosive industrial counterpart of *involuntary unemployment*. Unlike corporate industrial enterprise, agriculture, and especially a family farming system, does not have the organic will or the social influence to plough its redundant workers into the streets, and thereby either of compelling

³⁵ Fei and Ranis [10] have provided a relevant analytical framework with respect to this redundant farm-sector labor.

³⁶ This would be the case taking into account the costs of relocation which normally would be incurred by any farm labor that moves to the city in search of a job.

³⁷ Hendrix [23] [24] has contributed a very useful analysis of the nonfarm or general economy conditions which underlie the lack of alternative opportunities for underemployed labor resources in agriculture.

the innovation of more adequate complementary national development programs or of laying claim to publicly supported unemployment compensation for the human resources concerned.³⁸

While the discussion of surplus labor in agriculture normally centers upon the more densely populated underdeveloped countries, in order to complement previous figures it is instructive to consider that if, in the United States, all small-scale family farms were to be reorganized into efficient family farms by modern standards—that is, farms marketing at least \$10,000 worth of products—between 1½ and 2½ million farm families would be displaced from farming without any likely loss in aggregate farm production.³⁹ Undoubtedly, however, if the associated breadwinners were displaced from the farm sector, in the absence of some very dramatic and relevant nonfarm-sector adjustment and development programs, there would be a substantial increase in national unemployment figures. Were only 1½ million of the families which thus might be displaced from the farm sector in any serious attempt to raise the latter nearer to its real technological capacity unable to find employment elsewhere, the total present annual cost of their subsistence, whether financed from savings or from private or public transfer payments, would approximate \$4.5 billion at conservative nonfarm-sector costs of living.⁴⁰

Even in such a highly developed country as the United States, the recurrent charge upon the farm sector of the social welfare cost of supporting redundant farm labor, therefore, is quite considerable. However, there can be little doubt that it tends to be of even greater significance in countries at earlier stages of development and especially in such countries which also suffer from dense population ratios. Certainly, in many of these cases, it is of such proportion as to place the

³⁸ Recently Schultz [50, pp. 53-70] also has emphasized the implications which flow from the fact that redundant farm labor is absorbed into the fabric of the farm productive process and as such is not "free" labor. That is, the marginal productivity of surplus farm labor in agriculture may approach zero but, in underdeveloped countries especially, there still remains a problem of freeing it from the industry without a deleterious impact on agricultural production.

³⁹ The latter figure was suggested recently by Federal Budget Director Kermit Gordon [14, p. 27]. Higbee [25, p. 13] suggests that 2.2 million farms could go out of business between 1959 and 1969 and "their output would not be missed."

⁴⁰ Based on \$3,000 per annum, or about one half of the estimated, average, "moderate but adequate" cost of living for a family of four in large cities in 1959 [32]. Hendrix [24, p. 525] suggests that in 1959 the median net income of comparable workers in the nonfarm economy to the involuntarily unemployed labor in agriculture was \$3,200. Applying this figure to a more conservative estimate of underemployment in agriculture, namely, 1.1 million male farm workers in the 20 to 64 age bracket, he concludes that "if they had been as productively employed as were workers of comparable ability in the non-farm economy, they could have earned in the aggregate an additional income equivalent to about \$3.5 billion net farm income."

farm sector under a real, if not a crippling, handicap relative to the nonfarm sector in the matter of growth [48, p. 71]. Where it is so important as to stifle farm-sector growth entirely, the danger is that, through the backwash effects of sustained unbalanced growth, over-all development eventually will also be seriously impeded, if not also stifled.

At the same time it can be argued that, short of its having a crippling effect on over-all agricultural development, programs aimed at facilitating the outflow of labor from the farm sector probably deserve only low priority in the initial investment plans of underdeveloped countries. Indeed, purely on the grounds of comparative welfare costs, in many such cases there may be merit in policies aimed at discouraging a rapid flow of the latter into the narrow-based nonfarm sector,⁴¹ and this even at the cost of some form of welfare subsidy to the farm sector to assist it in the support of its redundant labor. The challenge in most of the underdeveloped countries is to find a way to effect the most efficient working compromise between the advantages of farm-sector-based social welfare for the poor and the developmental potential of adequate-sized family farms. This objective in most cases, no doubt, may best be realized through a deliberate creation of two sub-sectors in agriculture, one being designed to maximize the output of social welfare for surplus labor and the other to exploit the full dynamics of the Mill-Marshallian model in respect of development. This, of course, is precisely what has happened as a haphazard by-product of the process of development in the United States and other economically advanced countries. By accident more than by design the farm sectors in all of these countries comprise a minority of highly productive commercial farms and a large majority of essentially subsistence farms, with the former producing most of the surplus commodities and the latter supporting most of the surplus people.⁴² While there would seem to be little justification for the perpetuation of this phenomenon in countries at such an advanced stage of economic development as the United States, the idea of planned rural "slums"—a system of small holdings with associated, and socially subsidized, educational facilities,

⁴¹ The argument, while especially relevant to poor countries aspiring to a high rate of development, has a measure of general validity. As one writer has pointed out, "Until a nation needs its lands and labor, inefficient farmers may be better off where they are than if they were to head for the city's slums and welfare rolls. . . . To achieve a healthier agriculture at the expense of a sicker urban society is hardly a commendable objective" [25, p. 105].

⁴² For example, in the United States in 1959, 21.3 per cent of all farms supplied 71.8 per cent of all farm products sold on the market, while the remainder supplied only 28.2 per cent of the marketed products. These farms clearly supported most of the farm population [70].

public works, rural industries, and even supplementary welfare payments—may have considerable merit in the early stages of development.

III. *Utilizing the Spoils*

The superiority of the Mill-Marshallian model for the incorporation of the farm sector into the over-all development process from the point of view of promoting agricultural productivity appears very clear. It is also apparent that this model, in association with the more general phenomenon of "emigrant capital" and/or the assumption of the costs of supporting redundant farm labor, provides a very effective framework for the appropriation of the major fraction of the gains in farm productivity for other purposes than that of increasing farm incomes. At least in the case of the United States, most of the income differential between the farm and nonfarm population can be explained in these terms, leaving very little to account for purely in terms of economic inefficiencies in the performances of farm-sector factors or enterprises themselves.⁴³

The advantage of the Mill-Marshallian framework with regard to the matter of insuring a utilization of the appropriated potential for nonfarm-sector development purposes is not so obvious. Under the Marx-Leninist model the requisitioned food is subject to allocation within the framework of a centralized plan and to this extent can be purposively directed into development forms of utilization according to the general principle: to each according to his contribution to the fulfillment of the development plan.⁴⁴ By contrast, under the operation of the Mill-Marshallian model a substantial part of the potential is apt to be scattered among consumers in the nonfarm sector in the form of higher real incomes where, under the conditions which characterize most of the underdeveloped countries, it would appear more likely to be lost in the bottomless pit of underconsumption than translated into a higher rate of investment activity.

Countries successfully following the Mill-Marshallian model have all had to incorporate counteracting institutional influences within their social-economic structures to offset the potential impact of this nonfarm consumption leakage on its ultimate effectiveness as an instrument for capital accumulation and a high rate of over-all economic

⁴³ In this sense, Professor Schultz's claim [50, pp. 36-52] that "there are comparatively few significant inefficiencies in the allocation of the factors of production in traditional agriculture" [50, p. 37] turns out to be a proposition that can be applied quite generally, almost irrespective of the stage of development.

⁴⁴ The investment opportunity represented in food resources has been well argued by Matthew J. Kust [30].

growth.⁴⁵ Obviously important in this regard have been historical patterns of income distribution and the role of the corporation and of government in nonfarm savings and investment activities in these countries. However, for the benefit of underdeveloped countries which might aspire in the future to follow this model, especially significant would appear to be an innovation that Yugoslavia introduced in returning essentially to the Mill-Marshallian model after its abortive experiment with the Marx-Leninist model [3]. By placing the emphasis in agricultural production organization on the independent peasant proprietor supported by more voluntary cooperation, the Yugoslavs have been able, even on the basis of miniature farms, to gain the benefit of a superior record in agricultural productivity⁴⁶ in conjunction with relatively low food prices. However, the resulting diversion of income to the nonfarm sector has been treated, not as the end of the process, but merely as a means to a more effective mobilization of domestic savings. Thus, by applying a deliberately high differential rate of taxation in the urban-industrial economy, Yugoslavia has been able to raise its domestic savings to about 29 per cent of the social product and, with the aid of supplementary foreign resources, to maintain a level of investment as high as 35 per cent (1961) [11]. If an effective system of differential taxation can in this way be associated with the basic Mill-Marshallian model, its growth potentialities undoubtedly stand to be expanded very considerably over the record of most countries following this model to date.

IV. Conclusion

In conclusion, two implications of the above analysis deserve to be emphasized. First, the perpetuation of a substantial backlog of underutilized labor in the farm sector in the United States and in most of the richer countries attests mainly to the fact that the urban-industrial development programs in these countries have fallen far short of their potentialities, and correspondingly of the comparable record of performance provided by their farm sectors. Their record also has been more one of consuming the fat of the land than of utilizing it fully in the

⁴⁵In addition, while the record under the Mill-Marshallian model has not been as abortive in practice as this characteristic of the model might imply, neither has the direct administration of "food investment" proved to be as straightforward as it might appear to be at first sight. Putting this part of the Marx-Leninist model into practice has proved to be much easier said than done. Much light has been thrown on this problem by recent studies, such as that by the F.A.O. [62], related to the possibilities of utilizing accumulated and potential surpluses of agricultural products in the United States and elsewhere for developmental purposes in the poorer countries.

⁴⁶The compound annual rate of growth of total agricultural production in Yugoslavia over the period of 1952-62 was 6.1 per cent [7, p. 1054], a rate exceeded or approached by very few other countries.

promotion of over-all growth and development. It might be presumed that at such high levels of development a conscious effort to establish a higher degree of equality between farm and nonfarm incomes would be both merited and practical, and the fact that, in spite of all the farm programs, so little has been achieved in this way is worthy of serious thought.⁴⁷

However, and secondly, in the developing countries the emphasis clearly should be placed, not on immediate equity between farm and nonfarm incomes, but on the maximization of the growth rate in agriculture and the maximum immediate diversion of the resulting increments to the protection and support of the emerging nonfarm sector and of the generally differentiated and interdependent features of a more highly developed economy. That is, the identified Mill-Marshallian model has been described not primarily to show how agriculture tends to be an unduly exploited sector in economically advanced countries, but rather to identify a tested and relatively painless method whereby the inevitably "painful" or sacrificial process of domestic capital accumulation can be set in self-sustaining motion and progressively accelerated in a traditional, agrarian economy. But, first must come the will and the wit to effect those structural reforms which are necessary in most underdeveloped countries to condition the application of this method of accumulation.

HIDDEN UNEMPLOYMENT 1953-62: A QUANTITATIVE ANALYSIS BY AGE AND SEX

By THOMAS DERNBURG AND KENNETH STRAND*

Recent research [1] [2] [3] [4] shows that the loss of jobs owing to declining business activity is accompanied by the withdrawal of workers from the civilian labor force. Because of such withdrawal the labor force figures that are recorded during periods of economic slack are considerably smaller than the figures that would have been recorded had the economy been at full employment. The recorded level of unemployment and the unemployment rate therefore understate the true level of manpower underutilization during such periods. For example, our own work [1] indicates that the unemployment rate for 1962 rises to over 9 per cent when the number of persons who withdraw from (or never enter into) the labor force because of slack economic conditions are added back into labor force and unemployment statistics.

Some workers withdraw from the labor force because of the "discouraged worker" effect. Other workers, however, respond to "additional worker" pressure and therefore enter the labor force. The degree to which the two effects govern labor force participation depends upon the stage of the business cycle. A fall in employment from a cyclical peak is initially accompanied by a sharp decline in labor force participation. Thereafter additional falls in employment are accompanied by a considerably lower level of withdrawal because the discouraged-worker effect is partially offset by the influx of additional workers during later stages of recession. Put differently, as economic adversity continues, pressure builds up on additional workers whose entry into the labor force partially offsets the discouraged-worker effect.

The present paper reports the results of an attempt to answer the following questions: (1) Who are the discouraged workers who leave the labor force when employment declines? (2) Who are the additional work-

* The authors are, respectively, professor of economics at Oberlin College, and economist, Manpower and Social Affairs Directorate, Organization for Economic Co-operation and Development. Initial stages of the research were supported under a Ford Foundation Public Affairs grant to Oberlin College. The major source of support is a Brookings Institution Research Professorship that was awarded to one of the authors for the academic year 1964-65. Additional help came from the Yale-MIT growth project and from the Research Seminar in Quantitative Economics at the University of Michigan. Of the many persons who gave advice and criticism, particular votes of thanks are owed to Daniel B. Suits and James Tobin. The authors are grateful also for the support and hospitality that was extended to them by the Department of Economics at the University of Michigan.

ers who enter the labor force under the pressure of economic adversity? (3) What is the quantitative relationship between employment and labor force participation in these respective groups? (4) What are the additional employment requirements, both in the aggregate and for each group, that would achieve a 4 per cent over-all unemployment rate? (5) What unemployment rates, for the individual groups, would be associated with over-all full employment? (6) Has there been a structural shift in the composition of the labor force of a sort that might render the attainment of full employment more difficult?

I. Data and Variables

The analysis utilizes monthly Bureau of Labor Statistics (BLS) data of population, labor force, and employment, unadjusted for seasonal variation, as well as a series of new exhaustions of unemployment compensations of the Bureau of Employment Security.¹ Past experience points to the presence of such subtle and close timing relationships that monthly data are to be preferred to quarterly or annual data.

We are concerned with the adult, civilian, noninstitutional population, which we shall denote simply as "total population." Variables that are accompanied by subscripts denote values for a particular subset of the population. Thus L_i , E_i , and P_i are the number of persons in the labor force, the level of employment, and the population, respectively, in group i . Variables that are unaccompanied by subscripts denote aggregates. Therefore, P , E , L , and X represent total population, total employment, the total labor force, and the total number of new unemployment compensation exhaustions, respectively. The statistical analysis is in terms of ratios. We define:

L_i/P , the "group labor force participation ratio"—i.e., the ratio of labor force in group i to total population;²

E_i/P , the group employment ratio—i.e., the ratio of employment in group i to total population;

L/P , the aggregate labor force participation ratio;

E/P , the aggregate employment ratio; and

¹ Most of the data were provided directly from the Bureau of Labor Statistics through the kind cooperation of Mr. Harold Goldstein, Assistant Commissioner of Manpower Statistics, and Miss Gertrude Bancroft, Special Assistant to the Commissioner of Labor Statistics. Monthly series on Population, Labor Force, and Employment may be found in the Bureau's publication *Employment and Earnings* and in its *Monthly Report on the Labor Force*. Data for unemployment compensation exhaustions were provided by Mr. Robert C. Goodwin, Administrator of the Bureau of Employment Security. A rounded series may be found in *Health and Welfare Indicators*.

² The ratio of labor force to population within a group is customarily called a "labor force participation rate." Since we utilize group labor force to total population as our dependent variable, we hope to avoid confusion by calling the resulting statistic a "labor force participation ratio."

X/P , the exhaustions ratio—i.e., the ratio of new unemployment compensation exhaustions to total population.

II. *The Total Civilian Labor Force*

The results of the previously cited global study form an integral part of the present analysis. They serve, moreover, to introduce our general procedure and therefore provide a useful starting point. We attempt to explain the aggregate labor force participation ratio by means of an equation that embodies both the discouraged-worker and the additional-worker hypotheses and that also makes allowance for trend and for seasonal variation. The expression is:

$$(1) \quad \left(\frac{L}{P}\right)_t = a_m + a_1 \left(\frac{E}{P}\right)_t + a_2 \left(\frac{X}{P}\right)_{t+2} + a_3 \left(\frac{1}{P}\right)_t + r_{t1},$$

where r_{t1} is a residual-error term. Seasonal variation is taken into account by utilizing dummy variables in such a way that the intercept term, a_m , changes with the month of the year. Since a fall in the employment ratio is indicative of a loosening of the labor market, we expect the resulting relative scarcity of job opportunities to lead to discouragement and withdrawal from the labor force. The coefficient a_1 is therefore expected to be positive. Similarly, a positive value for the coefficient a_2 is taken to be evidence in support of the additional-worker hypothesis. When unemployment-compensation exhaustions of workers rise, pressure on additional workers to enter the labor force increases, and labor force participation therefore increases. Finally, statistical significance of the coefficient a_3 would indicate the presence of a secular trend in the labor force participation ratio.

The two-period lead of the exhaustions ratio reflects a statistical result that can be explained by the fact that the pressure on additional workers to enter the labor force in the face of unemployment on the part of the primary worker undoubtedly begins prior to the actual exhaustion of unemployment-compensation payments. Thus the pressure that exists in month t is, on the average, not reflected in the exhaustions data until two periods later.

Statistical analysis lends support to the hypotheses. For the period November 1952–December 1962, inclusive,³ we obtain:

$$(1a) \quad \left(\frac{L}{P}\right)_t = a_m + \underset{(.0367)}{.9490} \left(\frac{E}{P}\right)_t + \underset{(.735)}{12.699} \left(\frac{X}{P}\right)_{t+2} - \underset{(695.4)}{5326.1} \left(\frac{1}{P}\right)_t + r_{t1}.$$

³ The 122 observations are reduced to 120 by virtue of the two-period lead of the exhaustions ratio. All estimates in this paper are based on 120 observations.

The values in parentheses beneath the regression coefficients are the standard errors of the respective coefficients. The coefficient of determination⁴ and the standard error of estimate are, respectively, .8766 and .00206. The coefficients a_1 and a_2 have the expected signs, and both are statistically significant at the 1 per cent level. The coefficient a_3 , which permits gauging of secular changes in the participation ratio, is also statistically significant and, oddly enough, the sign of the coefficient is negative, thereby indicating that the labor force participation ratio, after allowance for adverse employment conditions, would have been observed as increasing over the period covered by the data.

Because the exhaustions ratio is a function of past employment (unemployment) levels, the coefficient a_1 cannot be interpreted as the derivative of labor force participation with respect to employment. We therefore add the second equation:

$$(2) \quad \left(\frac{X}{P}\right)_t = b_m + b_1 \left(\frac{E}{P}\right)_{t-1} + b_2 \left(\frac{X}{P}\right)_{t-1} + r_{t2},$$

which incorporates the hypothesis that the exhaustions ratio in month t is a function of all past employment ratios with the influence of each employment ratio diminishing geometrically as it recedes into the past. The population variable is not statistically significant. When we replace the coefficients with their numerical estimates, we have:

$$(2a) \quad \left(\frac{X}{P}\right)_t = b_m - .00419 \left(\frac{E}{P}\right)_{t-1} + .8829 \left(\frac{X}{P}\right)_{t-1} + r_{t2},$$

(.00175) (.0404)

with coefficient of determination, .9326, and standard error of estimate, .000115.

Equations (1) and (2) can be combined, and the effect on labor force participation of an instantaneous change from one stationary employment ratio to another can be calculated. The result is:

$$\frac{a_1(1 - b_2) + a_2b_1}{1 - b_2} = .4951,$$

and we therefore conclude that, over the decade covered by the data, one person appears to have left the labor force for every two who lost their jobs.

⁴ R^2 is the coefficient of determination about the monthly means rather than about the over-all mean. If D^2 is the coefficient of determination about the over-all mean and A^2 is the coefficient of determination obtained by regressing the dependent variable only upon the monthly dummy variables, then:

$$R^2 = \frac{D^2 - A^2}{1 - A^2}.$$

III. *The Age-Sex Division: Hypotheses*

In moving from the labor force as a whole to the individual age-sex groups we take equation (1) and replace the aggregate labor force participation ratio with the participation ratio of the specific group under analysis. Because the participation ratio of a specific group will vary if the fraction of the total population in that group changes, we add the variable $(P_i/P)_t$ in order to capture the effect of relative population shifts. The counterpart to equation (1) for group i therefore is written:

$$(3) \left(\frac{L_i}{P}\right)_t = a_{m_i} + a_{1i} \left(\frac{E}{P}\right)_t + a_{2i} \left(\frac{X}{P}\right)_{t+2} + a_{3i} \left(\frac{1}{P}\right)_t + a_{4i} \left(\frac{P_i}{P}\right)_t + r_{13i}$$

The pressure on additional workers to enter the labor force is, of course, likely to be reflected by the exhaustion of unemployment compensation of persons in other groups. It is therefore appropriate to retain the aggregate exhaustions ratio as a measure of additional-worker pressure. It is assumed that the two-period lead of the exhaustions ratio remains appropriate.

Variations in labor force participation in group i will be most closely correlated with variations in employment within the group. However, since our purpose is to study cyclical effects on labor force participation and since the discouraged-worker hypothesis relates to total labor market tightness, we prefer to utilize the aggregate employment ratio rather than the group specific-employment ratios. Differential changes in employment may take place between groups without being accompanied by any change in over-all labor market tightness. Consequently a statistical correlation between E_t and L_i would not constitute a clear-cut test of the discouraged-worker hypothesis.⁵

Answers to all of the questions that were posed at the outset of this paper cannot be obtained without an expression that relates total employment to group employment. We therefore specify:

⁵ There is another important reason why we should not regress L_i/P on E_i/P . Both variables are derived from the same sample. Because one constitutes a large fraction of the other, the two will show a high degree of correlation in the event that sampling and response errors are present. If the sample value of employment in a group is in excess of its true value, the chances are that the sample value of labor force for the group will probably also be in excess of its true value. Consequently the sample values of the variables will exhibit statistical correlation, the regression coefficients will be biased, and we would not know if a true association between group labor force and group employment exists.

The procedure of regression group labor force participation on aggregate employment helps to liberate us from this difficulty. Although for any subgroup of the population the sampling errors in the labor force and employment values are apt to be correlated, there is no reason to suppose that such correlation exists between the sampling errors in a particular subgroup of the labor force and the labor force as a whole. While L_i and E_i are likely to be correlated if sampling error is present, there is little reason to suppose that L_i and E , or E_i and E should also be correlated.

$$(4) \quad \left(\frac{E_i}{P}\right)_i = c_{mi} + c_{1i} \left(\frac{E}{P}\right)_i + c_{2i} \left(\frac{1}{P}\right)_i + c_{3i} \left(\frac{P_i}{P}\right)_i + r_{4i},$$

which, in conjunction with equations (2) and (3), permits us to observe the effect of a change in aggregate employment on group labor force participation and employment.

The statistical results for equations (3) and (4), covering the same period as the global analysis, are reported in Tables 1 and 2, respectively. Although there is no need to be concerned with the individual monthly intercept terms, we do need the average values which we report in column 1. The last column of each table gives the coefficients of determination. The intervening columns contain the regression coefficients and their respective standard errors. The purpose of the asterisks is to call attention to the fact that the coefficients they accompany are not statistically significant at the 5 per cent level of significance.

The results reported in Table 1 are our primary concern. Inspection of the a_{1i} coefficients, together with their respective standard errors, indicates that labor force participation is positively associated, in a statistically significant manner, with total employment in all but three of the groups. The discouraged-worker hypothesis is therefore consistent with the data in 11 of the 14 groups. All of the female groups evidently are subject to the discouraged-worker effect, while among men only the very young and the very old seem to be so affected.

The coefficient a_{2i} , as expected, is positive for all groups and is statistically significant in all but three of them. The additional-worker hypothesis is therefore consistent with the data in 11 of the 14 groups. Taking both effects into account, we conclude that labor force participation is virtually autonomous for males between the ages of 25 and 64, while substantial fluctuations in participation are observed in all female groups and especially among the youngest and oldest groups of both sexes.

Statistical significance of the coefficient a_{3i} suggests the presence of a trend in the participation ratios. Since this is the coefficient that accompanies the reciprocal of population variable, the predominantly positive signs for males indicate a secular decline in the male participation ratios, while the negative signs for women reflect the substantial rise in participation that has taken place among women during the decade.

The coefficient a_{4i} of the population ratio, P_i/P , is statistically significant in all but two groups. Because an increase in the population of a group relative to the total would always be expected to raise the group's participation ratio, it would have been most surprising if any of these coefficients had been significantly negative. The coefficients are, of

course, highest for the groups whose members are most likely to be in the labor force.

The results for equation (4) are reported in Table 2. A rise in total employment causes employment in all groups to rise. The lowest c_1 coefficients occur for males 55-64 and females 20-24. Presumably the

jobs of this group of males are more completely "fenced in" by seniority and other forms of job protection. The result for females 20-24 is an optical illusion that stems from the fact that the group's class interval is smaller than for the older groups. Actually there seems to be little difference between this group and the 25-34 group, although for both

65 and over	.0200	.0355 (.0050)	-2,680 (570)	-.1509 (.0684)	.5447

groups employment fluctuates less than in other female groups.

The c_{2i} coefficients are a statistical corroboration of the well-known fact that secularly group employment ratios have declined for males and increased for females. The c_{1i} coefficients, which reflect relative population changes are, as expected, positive. The lone exception is the 65-and-over female group where the coefficient is small both absolutely and relative to its standard error.

IV. *Stationary Derivatives and Elasticities*

Interpretation of the results is facilitated by the computation of a set of stationary derivatives and elasticities. Although the a_{1i} coefficients are generally positive, indicating that participation will rise when employment rises, such a change is accompanied by an offsetting additional-worker effect represented by the exhaustions ratio and we cannot, therefore, tell from inspecting Table 1 what the net effect will be. To remedy this circumstance we calculate the net effect of an instantaneous change in employment upon labor force participation. Substitution of the stationary form of equation (2) into equation (3), given the net effect of a change in total employment upon group labor force participation:

$$\frac{dL_i}{dE} = \frac{a_{1i}(1 - b_2) + a_{2i}b_1}{1 - b_2}.$$

Similarly, the effect of a change in total employment on group employment is:

$$\frac{dE_i}{dE} = c_{1i};$$

and finally, the relationship between group employment and group labor force participation is:

$$\frac{dL_i}{dE_i} = \frac{dL_i}{dE} \cdot \frac{dE}{dE_i} = \frac{a_{1i}(1 - b_2) + a_{2i}b_1}{c_{1i}(1 - b_2)}.$$

Numerical estimates are recorded in Table 3. Instead of reporting the actual derivatives, the table is arranged so that the effect of an increase in total employment of 1,000 may be observed. In column 1 we show the way the change in employment is distributed; column 2 presents the associated change in labor force participation; and column 3 shows the reduction in unemployment.

The asterisks in column 2 indicate that the computation is not based on a statistically significant relationship. Whether we assume that the regression coefficient a_{1i} is zero for these two male groups or is equal to

TABLE 3—EFFECT OF A RISE IN TOTAL EMPLOYMENT OF ONE THOUSAND
ON GROUP EMPLOYMENT AND LABOR FORCE PARTICIPATION

<i>GRAND TOTAL</i>	1,000	454	546

¹ The a_{11} coefficients have been multiplied by a factor of 1.033 in order to make the total increase in employment equal 1,000.

the computed value makes little difference. The effect on labor force participation of a change in employment for these two male groups is negligible.

Correct interpretation of the results necessitates recognition of the fact that the reported values are averages for the period as a whole. They should not be used to estimate the employment and labor force changes for any specific year. The averages show considerable variation in labor force participation among men aged 14-24 and for the 65-and-over group. The result for the male 55-64 group, although quantitatively small, is extremely interesting.⁶ This group is the only one in which the additional-worker effect overcomes the discouraged-worker effect. The result can be interpreted in a number of ways. First, it is possible that recession causes a disruption in the normal flow of retirements. Male workers in the 55-64 age group may utilize their seniority privileges to

⁶The regression coefficient a_{11} is not statistically significant in the male 55-64 age group. If we calculate the change in labor force participation, assuming that the true value is the .0107 reported in Table 1, we get the change in labor force participation of -9 reported in Table 3. On the other hand, if we assume the value of the coefficient to be zero and re-estimate the parameters with the employment ratio eliminated, we obtain a value of -13.

extend their working careers in order to assist hard-pressed relatives during times of economic adversity. Such workers may therefore be thought of as effecting a transition to additional worker without ever losing their jobs. Alternatively, it is possible that recession induces some persons who have retired early to return to the labor force.

For women there are sizable fluctuations in labor force participation in all groups. Among the youngest women, an increase in employment is accompanied by practically a one-for-one change in labor force participation. As is shown in column 3, it is practically impossible by increasing total employment to reduce unemployment in the female 14-19 group. The lowest change in participation is in the 20-24 bracket; the rise in labor force participation with respect to changes in employment then rises steadily as we proceed along the age spectrum.

The rise in employment of 1,000 is accompanied by a rise in employment of males of 564 and an increase in labor force participation of 148. Unemployment therefore declines by 416. Similarly, a rise in total employment of 1,000 increases female employment by 436 and leads to an increase in participation of 306. Thus the reduction in unemployment is only 130. Finally, the totals shown at the bottom of the table indicate that a total of 454 persons enter the labor force when employment rises by 1,000, which implies that unemployment declines by only 546.

To avoid misleading impressions that could arise from different-sized class intervals and from different-class population values, and to estimate the responsiveness of labor force participation to changes in employment, it is useful to convert the derivatives into elasticities. We define:

$$e_1 = \frac{dE_i}{dE} \frac{E}{E_i}, \quad e_2 = \frac{dL_i}{dE} \frac{E}{L_i}, \quad \text{and} \quad e_3 = \frac{e_2}{e_1} = \frac{dL_i}{dE_i} \frac{E_i}{L_i}.$$

The derivatives are the same as before. The absolute values of E , E_i , and L_i are the average values of these variables over the period covered by the data.

The numerical values of the derivatives are reported in Table 4. The elasticity of individual group employment with respect to total employment exhibits the saucer shape that we expect, i.e., it is highest for the very young and the very old and low in the middle ranges. This elasticity is also higher for women than for men. The elasticity of group labor force participation with respect to total employment (e_2) is also saucer-shaped, and the same is true for the elasticity of group labor force participation with respect to group employment (e_3).

The most striking result that emerges from inspection of these elasticities is that where group employment is highly responsive to changes in total employment, labor force participation is also highly responsive. The result suggests that the likelihood of discouragement and with-

drawal from the labor force is closely related to the degree of job security that workers normally enjoy.

V. Full-Employment Labor Force

We have shown that the recorded magnitude of the labor force during times of economic slack is considerably lower than it would have been had the economy been at full employment. It follows that the recorded level of unemployment for most age groups understates both the magnitude of the productive manpower loss that is created by recession and the additional jobs that are needed to restore full employment.

Following current usage we define "low full employment" and "high full employment" as situations that obtain when the measured seasonally adjusted aggregate unemployment rate is 4 and 3 per cent respectively. Full-employment labor force then becomes the size labor force which is associated with these respective unemployment rates. In what follows we concentrate on the low full-employment "criterion" rate of 4 per cent.

The problem of estimating the full-employment labor force is complicated by the presence of secular trends in the labor force participation ratios. Were it not for these trends we could utilize the stationary derivatives that were reported in Table 3 to compute full-employment labor

force. This could be done as follows: From the definition of the unemployment rate, $u = (L - E)/L$, we can derive:

$$dE = \frac{L}{(1 - u) \frac{dL}{dE} - 1} (du).$$

For 1962 $L = 71,854$ and $u = .056$. The required change in u is therefore $-.016$, and since $dL/dE = .454$, the required change in employment is 2,013 thousand. This would bring total employment to a level of 69,852 thousand. Since the accompanying change in labor force participation would be 914, total labor force would rise to 72,768 and the unemployment rate would be reduced to 4 per cent. The full-employment labor force estimate for 1962 would then be 72,768.

Calculated in the foregoing manner, the full-employment labor force estimates would overstate full-employment labor force for the early years of the period, underestimate it for the later years, and serve as a correct approximation only for the middle years. The cause of the discrepancy is the rising trend in the participation ratios that have been observed. Over the decade labor force participation has risen more rapidly than employment. Consequently, the unemployment rate has shown a secular increase, and the gap between actual labor force and full-employment labor force has grown wider. Had there been no secular trend in the unemployment rate, the procedure subsequently to be introduced would yield results identical to calculations based on average (stationary) values.

To make the project manageable and to convert our figures to a seasonally adjusted basis, we first remove the shifting monthly intercepts and treat them as constants by aggregating the equations over any consecutive 12-month period and dividing the resulting expressions by 12. The procedure, ignoring error terms, yields:

$$(3a) \quad \left(\frac{\bar{L}_t}{P}\right)_t = \bar{a}_t + a_1 \left(\frac{\bar{E}}{P}\right)_t + a_2 \left(\frac{\bar{X}}{P}\right)_{t+2} + a_3 \left(\frac{\bar{I}}{P}\right)_t + a_4 \left(\frac{\bar{P}_t}{P}\right)_t,$$

and:

$$(4a) \quad \left(\frac{\bar{E}_t}{P}\right)_t = \bar{e}_t + c_1 \left(\frac{\bar{E}}{P}\right)_t + c_2 \left(\frac{\bar{I}}{P}\right)_t + c_3 \left(\frac{\bar{P}_t}{P}\right)_t,$$

and where, for example,

$$\left(\frac{\bar{L}_t}{P}\right)_t = \frac{1}{12} \sum_{m=1}^{12} \left(\frac{\bar{L}_t}{P}\right)_m, \quad \text{and} \quad \bar{a}_t = \frac{1}{12} \sum_{m=1}^{12} a_{tm},$$

and t now dates the beginning of the seventh month of the 12-month period. This procedure transforms all of the variables into seasonally adjusted values obtained by a simple 12-month moving average. When the first month of the summation is January, the result provides an annual average.

If the aggregate employment and exhaustions ratios that are associated with an over-all 4 per cent unemployment rate can be found, they can be substituted into equations (3a) and (4a) in order to obtain the group labor force and employment ratios that are associated with low full employment. In deriving these estimates it is useful to resort to the global model.

After undertaking the same seasonal adjustment procedure as above, equations (1) and (2) become:

$$(1b) \quad \left(\frac{\bar{L}}{P}\right)_t = \bar{a} + a_1 \left(\frac{\bar{E}}{P}\right)_t + a_2 \left(\frac{\bar{X}}{P}\right)_{t+2} + a_3 \left(\frac{1}{P}\right)_t,$$

and;

$$(2b) \quad \left(\frac{\bar{X}}{P}\right)_t = \bar{b} + b_1 \left(\frac{\bar{E}}{P}\right)_{t-1} + b_2 \left(\frac{\bar{X}}{P}\right)_{t-1}.$$

When these expressions are combined with the criterion function

$$(5) \quad \bar{E}_1 = (1 - u)\bar{L}_t,$$

where u is the full-employment criterion unemployment rate, and the population function:

$$(6) \quad P_t = P_0(1 + r)^t,$$

there emerges the second-order nonhomogeneous difference equation:

$$(7) \quad A_0 \left(\frac{\bar{L}}{P}\right)_{t+1} + A_1 \left(\frac{\bar{L}}{P}\right)_t + A_2 \left(\frac{\bar{L}}{P}\right)_{t-1} = A_3 + \frac{A_4}{P_0(1 + r)^t},$$

where:

$$\begin{aligned} A_0 &= a_2 b_1 (1 - u), \\ A_1 &= -[1 - a_1(1 - u)], \\ A_2 &= b_2[1 - a_1(1 - u)], \\ A_3 &= \bar{a}(b_2 - 1) - a_2 \bar{b}, \text{ and} \\ A_4 &= [a_3[b_2(1 + r) - 1]](1 + r). \end{aligned}$$

Equation (7) has no stationary solution. However, it is possible to solve for the dynamic equilibrium path in order to obtain the full-employment labor force participation ratio as a function of time, the

estimated parameters, and whatever unemployment rate we wish to pick as our full-employment criterion. The solution is:

$$(8) \quad \left(\frac{\bar{L}}{P}\right)_t^* = \frac{A_3}{A_0 + A_1 + A_2} + \left[\frac{A_4}{A_0 + (1+r)A_1 + (1+r)^2A_2} \right] \left[\frac{1}{P_0(1+r)^t} \right].$$

The employment ratio that is associated with full employment follows immediately. It is:

$$(9) \quad \left(\frac{\bar{E}}{P}\right)_t^* = (1 - a) \left(\frac{\bar{L}}{P}\right)_t^*.$$

Finally, by returning to equations (1b) and (5) we obtain:

$$(10) \quad \left(\frac{\bar{X}}{P}\right)_{t+2}^* = -\frac{A_1}{a_2} \left(\frac{\bar{L}}{P}\right)_t^* - \frac{\bar{a}}{a_2} - \frac{a_3}{a_2} \left(\frac{1}{P}\right)_t,$$

for the full-employment exhaustions ratio.

Substitution of equations (9) and (10) into the set of equations (3a) provides the full-employment labor force estimates for the 14 groups. These full-employment labor force estimates, calculated on the basis of a 4 per cent criterion unemployment rate, are reported in Table 6. For purposes of comparison Table 5 presents the actual recorded values for labor force. Similarly, Table 7 reports actual unemployment rates, and the "manpower gap" unemployment rates are reported in Table 8. The manpower-gap rates are computed by subtracting actual employment from full-employment labor force and by dividing the resulting "manpower gap" (the sum of actual plus hidden unemployment) by full-employment labor force.

The main results can be summarized quite simply:

1. For the individual groups the excess of the gap unemployment rates over the actual unemployment rates is greatest in those groups that have the highest elasticity of labor force participation with respect to employment. Accordingly there is almost no difference between the actual and the gap rates for males 25-64. However for men 65 and over the gap rate, in recent years, far exceeds the actual unemployment rate, and for males 14-19 and 20-24 the gap rates exceed the already large actual rates.

2. The very high gap rates in recent years for the 20-24 group are clear evidence that the economy has not been creating new jobs at a rate that is high enough to absorb many of the potential new entrants into the labor force. There is a tendency to discount the enormously high rates in the 14-19 group with the argument that these boys should be

in school anyway;⁷ but one cannot dismiss the problem of the 20-24 group in this manner.

3. Among women the gap rates since 1958 have been uniformly higher than the actual rates. The large disparities that occur after 1960 reflect the fact that full-employment labor force participation has grown much more rapidly than female job opportunities.

4. The highest gap rates relative to the actual unemployment rates are found in those groups whose actual unemployment rates are already high relative to other groups. When labor force withdrawal is taken into account, the employment position of groups whose employment position is already unsatisfactory is accentuated relative to other groups.

5. Over the period covered by the data there is a fairly uniform tendency for the gap rates to increase both absolutely and relative to the measured unemployment rates. This results because the potential manpower pool has been growing more rapidly than the available number of jobs. The picture that emerges is one of steady deterioration in employment opportunities relative to requirements. The recovery of 1962 is barely perceptible in the gap rates, and in many cases the gap rates actually increased over the 1961 level.

6. For 1962 the level of unemployment for all men is 2,495 thousand and the manpower gap is 3,401 thousand. Hidden unemployment, defined as the difference between the manpower gap and measured unemployment, is therefore 906 thousand. For women the respective totals are 1,520, 2,934, and 1,414 thousands. For the labor force as a whole, therefore, hidden unemployment comes to 2,320 thousand. And these totals, it should be noted, are based upon the fairly unambitious definition of full employment as occurring when the over-all unemployment rate falls to 4 per cent. Had a 3 per cent unemployment rate been established as the full-employment criterion, the full-employment labor force, gap unemployment rates, and the level of hidden unemployment would all have been much higher.

VI. *Employment Requirements*

How many additional jobs would have been required in each group in order to reduce the over-all unemployment rate for 1962 to 4 per cent? According to our calculations, a 4 per cent unemployment rate implies a total labor force of 74,174. The level of employment would therefore

⁷ As far as the economist is concerned, the fact that an individual is productive enough to be gainfully employed when the economy is operating at full capacity ought to be sufficient evidence that if he does not have a job one ought to be found or created for him. Moreover, school is unfortunately not the only alternative to work for young persons. Although the labor force participation rates for 16-17 year old males who are enrolled in school have remained fairly constant, participation rates for those who are not in school have fallen steadily in the last few years.

have had to rise to 71,207 thousand. Since the actual level of employment was 67,839 thousand, the total number of additional job requirements was 3,368 thousand. The distribution of these additional job requirements can be calculated by making appropriate substitutions into equations (4a). The calculations are shown in Table 9. Column 1 reports full-employment labor force. Column 2 gives the actual employment values. Column 3 gives the distribution of employment when the overall unemployment rate is 4 per cent. And column 4 shows the distribution of the additional employment requirements.

Inspection of Table 9 indicates that an additional 3,368 thousand jobs are required merely to reduce the unemployment rate to 4 per cent. If a rise in employment is not accompanied by a change in labor force participation so that the 1962 labor force total of 71,854 remains frozen when employment increases, full employment would require 68,980 thousand jobs, which would mean the addition of only 1,141 thousand more jobs. If we call this figure the "overt" additional requirement, the "hidden" additional requirement, defined as the difference between the total additional requirement and the overt requirement, comes to 2,217 thousand.

VII. *Residual Unemployment*

If the over-all unemployment rate had been at the low full-employment level of 4 per cent in 1962, what would have been the status of the individual groups? Subtraction of the entries in the "full employment" column of Table 9 from the corresponding full-employment labor force figures gives the remaining level of unemployment in each group. These "residual" unemployment levels are then divided by the respective full-employment labor force values in order to arrive at the unemployment rates for the individual groups that are associated with an over-all 4 per cent unemployment rate. These "residual unemployment rates" are reported in Table 10.

TABLE 10—RESIDUAL UNEMPLOYMENT RATES AT LOW FULL EMPLOYMENT
1954 AND 1962

	Male		Female		Both Sexes	
	1954	1962	1954	1962	1954	1962
14-19	10.6	11.6	10.2	13.6	10.4	12.4
20-24	5.9	3.8	5.3	8.1	5.6	5.5
25-34	3.4	2.0	4.2	4.8	3.6	2.9
35-44	2.9	1.9	3.6	4.5	3.2	2.7
45-54	2.9	1.7	2.9	3.5	2.9	2.4
55-64	3.4	3.3	3.3	3.0	3.3	3.2
65 and over	3.2	4.3	2.0	4.3	3.0	4.3
TOTAL	3.8	3.2	4.4	5.6	4.0	4.0

A glance at the residual unemployment rates indicates that a reduction of the over-all unemployment rate to 4 per cent will still leave many groups with fairly high levels of unemployment. Although the position for most male groups would be satisfactory, the unemployment rate for males 14-19 would remain alarmingly high. For women the situation is less satisfactory relative to the comparable male class in all but two cases.

A comparison of the distribution of the residual unemployment rates for 1962 with comparable calculations for 1954 brings some important trends to light. The comparisons are presented in Table 10. A glance at the table confirms that for the males in the prime working ages, 20-64, the unemployment rates are lower than they were in 1954, while the opposite is, of course, the case for the extreme age groups. The table also shows the presence of a similar, though less-pronounced, pattern for women and therefore also when the data for both sexes are pooled. The totals in the bottom row show that the spread between the residual unemployment rates for men and women has widened considerably. Therefore if the economy had succeeded in reducing the unemploy-

ment rate to 4 per cent in 1962, additional employment would have had to come to a larger extent from women than from men and from the extremes of the age spectrum as opposed to the middle.

Unemployment rates may be somewhat misleading because a high unemployment rate for a particular group does not necessarily imply the presence of a large pool of available manpower. It is instructive therefore to compute "relative residual unemployment" levels that are associated with an over-all 4 per cent unemployment rate. By relative unemployment is meant that fraction of total unemployment that will be present in the group. As is shown in Table 11, the comparison between 1954 and 1962 for males becomes even more dramatic than before. In 1954 almost 36 per cent of residual unemployment would have

TABLE 11—RELATIVE RESIDUAL UNEMPLOYMENT AT LOW FULL EMPLOYMENT
1954 AND 1962

65 and over	3.2	3.5	.6	1.5	3.8	5.0
TOTAL	65.9	51.6	34.1	48.4	100.0	100.0

been men between the ages of 25 and 54, whereas for 1962 the total would have been only 19 per cent. Similarly, when the totals for men and women are computed, it appears that in 1954 residual unemployment would have been split in a ratio of 66 to 34 among men and women respectively, whereas by 1962 the division would have been almost equal.

Over the period for which the comparison has been made we have had a relative rise in full-employment labor force participation in those parts of the labor force that may be relatively less employable. On the one hand, this means that the achievement of a 4 per cent unemployment rate would put males in the prime working ages into an extremely favorable employment position. On the other hand, these trends may be interpreted as indicating that it might have become somewhat more difficult to reduce the over-all unemployment rate. The case is by no means clear-cut; however, if manpower must be drawn from the young (who probably require more training than the average worker), the old

(whose productivity may be lower), and from women (who legally can no longer be paid lower wages than men), the expansion of employment might raise costs and prices more rapidly than would have been the case had there been an available pool of males in the prime working ages.

We must emphasize most strongly that the discussion of this section is based on the pattern that would have emerged had the economy been at full employment. Since we remain a considerable distance away from that goal, it would be a mistake to infer from the discussion that demand expansion will pull up costs and prices because of a change in the structure of the labor force. Indeed, if a policy conclusion emerges from the analysis, it is that the enormous employment requirements that we face call for demand expansion on a large scale.

VIII. *Summary*

We have attempted to test the discouraged- and additional-worker hypotheses of labor force participation and have found each hypothesis to be consistent with the data in 11 of the 14 groups. Labor force participation is virtually autonomous for males 25-64. However, for the younger and older male groups and for all female groups, participation responds to changes in the level of employment. The direction of change in all cases except for males 55-64 is such that a rise in employment is accompanied by a rise in labor force participation. The responsiveness of labor force participation to changes in employment is greatest for the groups in which the elasticity of group to total employment is high. An increase in employment of 1,000 brings forth additional labor force participation of 454, on the average, so that the fall in unemployment is only 546.

Calculations of full-employment labor force and gap unemployment rates confirm the presence of considerable discrepancies between actual and full-employment labor force and between actual and gap unemployment rates for many groups. For 1962 the over-all gap rate is 8.5 per cent as opposed to an actual rate of 5.6 per cent. The discrepancies are particularly great for the very young and the very old and show a rising trend for females.

The attainment of a 4 per cent unemployment rate for 1962 would have necessitated the creation of over three million additional jobs. Had this additional employment been forthcoming, the remaining unemployment would have been split about evenly between males and females. This contrasts with a split of 66 per cent to 34 per cent for 1954. Also since 1954 there has been a relative decline in the residual unemployment rates for the middle ranges of the age spectrum and a corresponding increase at the extremes. The economy has not yet been able to

adjust to the sizable shifts in the structure of the labor force that have taken place over the decade.

CONCENTRATION AND LABOR EARNINGS

By LEONARD W. WEISS*

There have been periodic suggestions in the literature that concentrated industries may tend to pay exceptional wages [3] [6] [8] [10] [14] [16] [17]. If such a hypothesis could be given convincing support, it would have important implications for the evaluation of industrial performance. It would mean that the sum of monopoly rents would exceed greatly those identified in examinations of corporate profits. The resulting misallocation of resources would be understated even more seriously since the welfare loss due to monopoly pricing increases as the square of the margin between price and the opportunity cost of factors employed [7].

It has proved difficult to test for monopoly rents accruing to labor in concentrated industries because of the large number of variables pertinent to wage determination, many of which are correlated with industry structure. A number of studies have attempted to circumvent this difficulty by investigating wage changes [6] [8], but these really tested the distinct hypothesis that concentrated industries continuously increase wages relative to unconcentrated industries. Another investigator attempted to test the "monopoly wage" hypothesis by comparing the ratios of Canadian to U. S. wages in industries that were concentrated in Canada but not in the United States with other industries that were unconcentrated in both countries. His whole argument ultimately depended on nine mostly minor industries [13]. Altogether, it is doubtful whether many have been convinced by the evidence to date of either the presence or absence of monopoly rents in the wage payments of concentrated industries.

This paper attempts a new, direct test of the "monopoly wage" hypothesis using the 1/1000 sample of the 1960 Census of Population. The paper is divided into five parts. The first briefly reviews possible hypotheses. Part II describes the data; Part III presents the detailed results of multiple regression studies for semiskilled labor; and Part IV summarizes similar results for a number of other occupation groups. Part V presents some conclusions.

* The author is professor of economics at the University of Wisconsin. This paper was prepared under a grant from the Graduate School of the University of Wisconsin. Computations were partially financed by the Social Systems Research Institute and by the National Science Foundation. Comments by Glen Cain, Hirschel Kasper, H. Gregg Lewis, and Gerald Somers were very helpful in the preparation of the study.

I. *The Hypothesis*

The notion that monopoly on product markets leads to high payments for hired factors does not arise automatically from the concept of a profit-maximizing firm. Indeed, simple theory might suggest low rather than high wages in concentrated industries since output restriction would carry with it a restriction of employment. It is quite possible to find plausible arguments to support the opposite hypothesis, however. The profit-maximization assumption need not yield equally good predictions in all areas. Pecuniary profit motives might well be weaker in wage policy than in other business decisions. While high profits won by technical advance or effective market forecasts often enjoy general approval, high profits attained by paying meager wages almost certainly will win censure for the entrepreneur. A relatively profitable firm might well pay above-average wages to avoid such opprobrium, i.e., firms with exceptional profits might choose to use part of their earnings to buy public approval. This might be particularly true of firms with monopoly power because of their vulnerability to a bad press.

Even on the assumption of unequivocal profit-maximization, a high-wage policy might be plausible. Industries with high profits, whether due to monopoly or other causes, might attract trade unionism since they offer large prizes to the successful organizer. High wages might then result from the unionization of profitable industries or from managerial attempts to forestall such organization. Less-profitable industries might pay lower wages because the threat of organization might be less and/or because the firm might be less willing to pay to keep the union weak.

The increase in costs associated with a high-wage policy would probably not be as great as the increase in hourly wage rates in any event, since low wages would tend to result in high turnover, poor discipline, and poor-quality labor. A large, profitable firm which did pay high wages to buy public favor and/or to limit union power would have to pay less per "productivity unit" than per man-hour for its purchase.

In a perfectly competitive labor market an employer paying a high annual wage would get correspondingly superior workers. High earnings would not imply monopoly rents since laborers would still earn the values of their alternative products. While the tendency for labor quality to be related to earnings has long been recognized, some economists have doubted that it could fully account for interindustry wage differences. For instance, Sumner Slichter argued that if employers actually believed that higher wages brought them proportionately higher quality labor, the employers under the greatest competitive pressure would pay high rather than low wage rates [15, p. 90].

This paper tries to test two hypotheses: (1) that concentrated industries pay high annual rates for labor of particular "occupations"; and

(2) that these high earnings are more than can be accounted for by the personal characteristics of the labor employed. Most previous studies have been limited by the data to the first hypothesis. The 1/1000 Census tape makes it possible to test both.

Since concentration and unionization are closely related, they must both be considered. The effect of unionism with varying degrees of product market monopoly may be complex. In unconcentrated industries, strong union power might yield high wages, but in concentrated industries, where wages may already be high, unions may not add much. For one thing, if high wages in unorganized but concentrated industries result from the threat of unionism, then concentration and unionization would represent the same force. If this is true, the combined effects of concentration and unionization would be less than the sum of the effects of the two taken separately. In addition, unions seem likely to have greater bargaining power where they are the source of monopoly power on product markets—e.g., coal or construction—than where market power would exist without them—e.g., automobiles or steel [11, p. 138].

On the basis of these arguments, this study uses the model:

$$(1) \quad Y = b_0 + b_1 CR + b_2 U + b_3 U \cdot CR$$

where Y is annual earnings, CR is the concentration ratio, and U is the extent of collective bargaining coverage, to test for the existence of "monopoly wages" in concentrated and/or unionized industries.¹ The above argument suggests positive signs for b_1 and b_2 and a negative sign for b_3 . The monopoly-wage hypothesis would be supported in some form if b_1 were positive and large relative to b_3 . It would also be supported if b_1 and b_3 were both positive or, even if b_1 were negative, if b_3 were large and positive. The monopoly-wage hypothesis would have to be rejected if b_1 and b_3 were both negative or if either b_1 or b_3 were negative and large relative to the other.²

Concentration and/or unionization may be proxies for other industry characteristics. These other variables must also be introduced.

1. One might expect industries with rapidly increasing employment to show higher earnings than others, on the assumption that relative changes in employment opportunities are not perfectly foreseen by workers and that the short-run supply of labor in particular industries is not perfectly elastic. In effect, we assume that an increase in employ-

¹ This model had been formulated before the author saw the similar results of H. G. Lewis, [9, pp. 161, 178].

² Since the partial derivative of Y with respect to CR is $\partial Y / \partial CR = b_1 + b_3 U$, the net effect of CR on Y will change sign when $U = -b_1/b_3$. If this number falls between 0 and +100 (the range of U as it will be measured here), the monopoly-wage hypothesis will be confirmed over only a portion of the feasible range of U . It will be confirmed over the higher values of U where b_3 is positive and the lower values of U where b_3 is negative. By similar reasoning, the effect of unionization on earnings would change sign where $CR = -b_2/b_3$.

ment in any one industry represents an increase in demand rather than supply. This appears reasonable when large groups of workers employable in many different industries are involved.

2. There may be some justification for distinguishing durable- from nondurable-goods industries. The former are less stable over the cycle and would yield higher earnings in boom years to offset long periods of unemployment. In addition, there is a tradition that durable-goods industries require heavier work presumably implying better pay.

3. It is commonly supposed that large employers pay high wages. At first glance one might expect large employers to be associated with monopsony power, but this need not be so because they tend to be located in large labor markets. Many of the arguments for the monopoly-wage hypothesis can also be used to argue for high earnings in large shops.

4. Some argue that the over-all labor force characteristics affect industry wage rates paid [15]. E.g., earnings of a male worker would be lower in an industry with a large proportion of female workers than in one where most workers were male. This might occur if personnel policies or collective bargaining agreements apply the terms appropriate to the main core of the work force to all workers in a shop. Again, if all firms in an industry must meet one another's product prices, they may be forced by competition into similar wage policies. E.g., a firm in the North may pay low wages if a large proportion of its competitors are in the South. The five labor force characteristics for which this sort of argument seems most plausible are the percentages of the labor force that are (a) male, (b) skilled, (c) white, (d) in the South, and (e) of nonurban residence.

Finally, there are many personal characteristics important in the determination of labor earnings. There seem to be good reasons to expect that a person's age, race, region, urban or rural residence, mobility, education, intelligence, health, strength, manual dexterity, and appearance will affect his potential earnings in alternative employments, and therefore the minimum payments that his employer must make to get his services. Since the purpose of this paper is to determine the extent of monopoly rents included in labor earnings, it is important to introduce these personal variables. Even if earnings were high in concentrated or heavily unionized industries, workers would not be earning monopoly rents if their exceptional incomes could be wholly accounted for by exceptional personal attributes.

II. *The Data*

The dependent variable throughout this study is the private wage and salary income in 1959 reported by individuals in the 1/1000 sample

of the 1960 Census (see [4]). The populations used consist of all persons of specified occupation and sex employed for more than 13 weeks during 1959 and reporting their main employment in April, 1960 in (a) mining, construction, or manufacturing, or in (b) mining, construction, manufacturing, transportation, communications, or public utilities.³ The regulated industries were excluded from population (a) because concentration and unionization seemed likely to have different effects on wages with and without regulation. When population (b) was used, a dummy variable was introduced with a value of one when the industry involved was regulated. Agriculture, distribution, and services were excluded from the study because the large numbers self-employed and, at least in agriculture, the large amounts of nonwage income made it difficult to compare earnings with other industries.

The year 1959 is an adequate, though not perfect, year for our purposes. It falls at the end of a long, stable prosperity, so adjustments to the open inflation of the 1940's should be largely complete. There is evidence that neither monopoly nor union power was fully exploited during the 1940's and that they were re-exerted during the 1950's [1] [3] [5] [8] [9, p. 193] [19]. If there were monopoly-wage advantages, therefore, they were more likely to show up in 1959 than in earlier years. On the other hand, 1959 annual earnings are affected by the unemployment remaining after the 1958 recession and, in certain industries, by the long 1959 steel strike. The effect of unemployment is at least partially corrected by including the numbers of weeks worked in 1959 as variables.

Some fuzziness is introduced because characteristics are reported as of April, 1960, while earnings refer to 1959. Most personal characteristics (e.g., sex or education) remain stable from one year to the next, but in some cases incomes are reported for persons with different 1959 industries, occupations, or residences from those used. The most serious error of this sort is probably in the number of hours worked. These refer to "last week" (usually in March or April, 1960) and can differ sharply from the average weekly hours in 1959.

Each individual is assigned the characteristics of the industry that he reported. For instance, everyone employed in the shoe industry is assigned the shoe industry's indexes of concentration, unionization, growth, plant size, durability, and labor force characteristics as well as his own personal characteristics. The five labor force variables are derived from the 1/1000 sample itself, and the employment-growth variable is the 1960 industry employment divided by the 1950 industry employment, both taken from Censuses of Population. Industry defini-

³ Persons employed in industry 249, not specified metal industries, 326, not specified food industries, 459, not specified manufacturing, and 579, not specified utilities, were excluded.

tions involve no problems for these six variables.⁴ However, the indexes of concentration, unionization, and employer size are based on weighted averages of the component three- and four-digit industry figures using employment reported in the 1960 *Annual Survey of Manufactures* or *Employment and Earnings* as weights.

Two concentration indexes are used. The simplest is just a weighted average of 1958 four-firm concentration ratios by four-digit product class. These are imperfect indexes of market power because of the varying regional character of the markets for some commodities and the varying extent of noncompeting subproducts for others. A second concentration index identified hereafter as CCR (corrected concentration ratio) is also computed using weighted averages of five-digit concentration ratios for noncompeting subproducts and an arbitrary scaling-up of national concentration ratios in industries with clearly regional or local markets.⁵ These corrections are far from perfect, but the values of CCR should measure market power on a more nearly uniform basis in interindustry comparisons than those of the uncorrected average concentration ratios.⁶

The employer-size index is the percentage of employees in establishments with 250 or more employees in 1958. Establishments are used instead of firms because (1) employer size seems to be mainly a matter of his impact on local labor markets which depends on the size of his plants rather than his whole firm; (2) establishments are more accurately assigned to industries than firms are; and (3) because plant-size data are available for more industries than are firm-size data. The cut-off size of 250 employees is selected as a point by which impersonal employment relationships are likely to have developed. A further reason for using establishments rather than firms and for using 250 rather than a larger number of employees is to reduce the colinearity between the concentration and plant-size variables. There is undoubtedly some effect of employer bigness that cannot be distinguished from market concentration, but the measure used here does separate out important elements of employer size.

The existing measures of union power by industry are incomplete and often conflicting. Special estimates were developed for this study based on a wide range of sources. The BLS *Industry Wage Surveys* were taken as the basic source where available, and estimates based on other ma-

⁴ In industry 347, "Textile Dyeing and Finishing, Except Wool and Knit Goods," the population Census figure is wildly different from the Annual Survey of Manufactures figures for the same years. In that case a special figure derived from the Annual Survey of Manufactures was used.

⁵ The procedures used were approximately those used in [18].

⁶ The corrections used are described in more detail in an appendix available on request from the writer, Economics Department, University of Wisconsin, Madison, Wisconsin 53706.

terials were adjusted to the concepts used in those Surveys.⁷ Conceptually, union power in an industry is measured by the percentage of employees in establishments where more than half of the production workers are covered by collective bargaining agreements. The collective-bargaining-coverage approach does not distinguish between plants organized by locals of national unions and those organized by independent locals, nor between plants where all production workers are union members and those with collective bargaining agreements covering many nonunion members. Moreover, all employees in an industry are assigned the same collective-bargaining-coverage index regardless of whether or not they are themselves covered. There may be a tendency for our index to overstate unionism in industries with many small firms [9, pp. 273-75 and correspondence with Lewis], though the employer-size variable should pick up much of the effect of unionism missed for this reason.

An industry-wide measure of unionism seems appropriate in industries selling on national markets. Earnings at nonunion plants in highly unionized industries would tend to be high owing to the threat of unionism, and earnings at organized plants in industries where unions are weak would tend to be low because of competitive pressures. In localized industries, however, the *national* extent of collective bargaining coverage is, in effect, a weighted average of local-contract-coverage percentages. Such an average may be a poor union power variable if unionization varies greatly from locality to locality. Happily, the majority of observations in our study are in industries selling on national markets.

Regressions are computed for (a) unregulated industries and (b) regulated and unregulated industries together for the following four broad Census occupation and sex classes:

- 301-370 Clerical and Kindred Workers (Females only)
- 401-545 Craftsmen, Foremen, and Kindred Workers (Males only)
- 601-775 Operatives and Kindred Workers (Males only)
- 960-985 Laborers Except Farm and Mine (Males only)

In addition, regressions are computed for the unregulated industries only for the following, more narrow Census occupation-sex classes:

- 074 Draftsmen (Males only)
- 085 Mechanical Engineers (Males only)
- 290 Managers, Officials, and Proprietors, N.E.C. (Males only)
- 360 Typists (Females only)
- 465 Machinists (Males only)
- 715 Truck and Tractor Drivers (Males only)

⁷ The sources and techniques used are described in an appendix available from the writer on request (see n. 6).

- 775 Operatives and Kindred Workers, N.E.C. (Males only)
- 775 Operatives and Kindred Workers, N.E.C. (Females only)
- 834 Janitors and Sextons (Males only)
- 985 Laborers, N.E.C. (Males only)

Most other detailed occupations are specific to particular industries. Indeed, even this list contains several lopsided samples: 42 per cent of the "Laborers, N.E.C." and 30 per cent of the "Truck and Tractor Drivers" are in industry 196 "Construction"; 34 per cent of the machinists, 21 per cent of the mechanical engineers, and 18 per cent of the draftsmen are in industry 258 "Miscellaneous Machinery," and 22 per cent of the female operatives are in industry 359 "Apparel and Accessories." The distribution of the four broad occupation classes among industries is closer to the distribution of the entire work force, but here the diversity of included occupations may introduce a great deal of unexplained variability. These problems are both near a minimum in the case of occupation class 601-775 "Operatives and Kindred Workers." In view of the relative ease with which new semiskilled trades can be learned, it seems more appropriate to treat operatives as a homogeneous group of workers than to treat craftsmen or clerical workers that way. Occupation class 601-775 also avoids the overweighting of construction that occurs in the case of "laborers" (960-985). Moreover, the estimates of unionism which refer to percentages of production workers seem to apply more accurately to operatives than to other occupations. The unregulated industries probably provide the more useful sample for our purposes because concentration has a clearer meaning there, since our estimates of the unionism variable are more solid there, and because 47 per cent of the "operatives" in the regulated industries are in the rather special group "Truck and Tractor Drivers." Male operatives in unregulated industries are used in Part III of the paper to illustrate the statistical analysis used. Results for other populations are summarized in tabular form in Part IV.

III. *Regression Results for Semiskilled Males*

Regression coefficients relating total 1959 private wage and salary earnings to concentration and unionization for male operatives in unregulated industries are shown in Table 1. Two sets of coefficients are shown, one using uncorrected average concentration ratios (*CR*) and the other using corrected average concentration ratios (*CCR*). The second set of regressions seems most reliable on a priori grounds. Although the adjustments are rough, *CCR* surely comes closer to measuring market power on a basis comparable among industries than the uncorrected index. All of the regression coefficients are statistically significant and have the initially expected signs. The effect of concentration

TABLE 1—REGRESSION AND CORRELATION COEFFICIENTS RELATING 1959 WAGE AND SALARY INCOME TO CONCENTRATION AND UNIONIZATION FOR MALE OPERATIVES AND KINDRED WORKERS IN UNREGULATED INDUSTRIES
(OCCUPATIONS 601-775 IN INDUSTRIES 126-438)

<i>N</i> = 5187

Using <i>CR</i> : 4419	3872 (62.51)	16.70 (1.664)			.0189
	3248 (110.2)	11.04 (1.851)	11.75 (1.712)		.0275
	2691 (246.9)	31.90 (8.468)	19.26 (3.434)	-.2659 (.1053)	.0285
Using <i>CCR</i> : 4419	3358 (84.34)	26.53 (1.967)			.0337
	3039 (112.8)	21.40 (2.304)	7.606 (1.790)		.0369
	1936 (280.5)	53.47 (7.811)	23.74 (4.159)	-.4426 (.1030)	.0401

is unequivocally positive. The marginal effect of unionization is positive if *CR* is less than 72 or if *CCR* is less than 54.

The apparent effect of unionization and concentration are computed in Table 2 for two illustrative values of *CCR* and *U*. The particular values of *CCR* and *U* are selected as "high" and "low" values in each case. Values of *CCR* are below 20 for only 9 per cent of the male operatives in unregulated industries and above 60 for only 8 per cent. Values of *U* are below 50 for 17 per cent of these observations and above 90 for 14 per cent. Unionization seems to raise annual earnings by about 16 per cent when concentration is low, but to have no effect when *CCR* is high. Concentration seems to raise earnings by about 33 per cent when

TABLE 2—ESTIMATED VALUES OF *V* FOR CERTAIN VALUES OF *CCR* AND *U*

	Value of <i>U</i>	
	50	90
Value of 20	3750	4345
<i>CCR</i> } 60	5003	4891

unions are weak, but by only 13 per cent when they are strong. Disregarding other variables, the monopoly rents included in labor income could be very large.

When other industry characteristics are introduced as additional variables, the effects of CCR and U on Y are reduced. The equation becomes:

$$(2) \quad Y = 1751 + 20.13CCR + 10.15U - .08907U \cdot CCR + 5.494G \\ (349.7) \quad (9.259) \quad (4.845) \quad (.1268) \quad (.9169) \\ + 4.253L - 401.8D + 7.372M + 5.997Sk \quad R^2 = .0491 \\ (1.929) \quad (83.47) \quad (2.694) \quad (3.278)$$

where G is 1960 employment/1950 employment, L is the percentage of employees in establishments with 250 or more employees, D is a dummy with a value of 1 if the product is durable, M is the percentage of the labor force that is male, and Sk is the percentage of production workers who are skilled (the number in occupations 401-545 as a percentage of the number in occupations 401-985). All of these industry characteristics have significant effects on earnings except for the interaction term ($U \cdot CCR$) and the percentage skilled (Sk). All have the expected signs except durability. Taken by itself, durability is positively related to earnings, but it becomes negative when other industry variables are introduced. This is partly due to the relatively depressed conditions and the steel strike of 1959. Although the coefficients of CCR and U are both reduced, they remain statistically significant. Earnings now rise with either CCR or U over the entire observed range. Values of Y computed from this new equation are shown in Table 3 for the same illustrative values of CCR and U that were used in Table 2, assigning mean values to G , L , M , and Sk and zero to D . Taking other industry variables into account, unionization seems to add about 9 per cent to annual earnings when concentration is low and 4 per cent when it is high. Concentration adds 16 per cent to earnings when unions are weak, but 11 per cent when they are strong.

Thirty-one personal characteristics and three more industry characteristics are next added to form a third regression. The new industry characteristics are the white, rural, and Southern shares of the labor force. The sex and skill composition of the labor force are pure industry

TABLE 3—VALUES OF Y IN NONDURABLE-GOODS INDUSTRIES USING CERTAIN VALUES OF CCR AND U AND MEAN VALUES FOR OTHER INDUSTRY CHARACTERISTICS

Value of CCR	Value of U	
	50	90
20	4215	4576
60	4869	5061

characteristics because only semiskilled males are in our population, but the white, rural, and Southern shares of the labor force include elements of personal as well as industry characteristics until the corresponding personal characteristics are introduced.

The third equation with descriptions of the new variables used is listed below:

$$\begin{aligned}
 (3) \quad Y = & -156.2 + .2930CCR + 6.167U + .06872U \cdot CCR + .6150G + 2.622L \\

 & (183.40) \quad \text{(Variable 25)} \\
 & -1134. \quad \text{Dummy with a value of one if not the principle source} \\
 & (83.97) \quad \text{of support of the family (Variable 26)}
 \end{aligned}$$

291.9 (46.22)	Family size (in numbers of persons) (Variable 27)
-23.12 (4.463)	Family size squared (Variable 28)
56.21 (117.70)	Dummy with a value of one if moved since 1955 from an urban county in the same or contiguous state (Variable 29)
-441.5 (145.9)	Dummy with a value of one if moved since 1955 from an urban county in another state that is not contiguous to present state of residence (Variable 30)
-223.4 (69.83)	Dummy with a value of one if moved since 1955 from a non-SMSA residence (Variable 31)
243.10 (70.32)	Dummy with a value of one if native born with at least one foreign born parent (Variable 32)
-392.2 (107.6)	Dummy with a value of one if worked 15-29 hours "last week" (usually in the first half of April, 1960) (Variable 33)
-214.0 (134.3)	Dummy with a value of one if worked 30-34 hours "last week" (Variable 34)
-35.10 (130.5)	Dummy with a value of one if worked 35-39 hours "last week" (Variable 35)
131.0 (70.27)	Dummy with a value of one if worked 41-48 hours "last week" (Variable 36)
349.8 (101.8)	Dummy with a value of one if worked 49-59 hours "last week" (Variable 37)
250.1 (133.6)	Dummy with a value of one if worked 60 or more (Variable 38)
-2095. (120.7)	Dummy with a value of one if worked 14-26 weeks in 1959 (Variable 39)
-1501. (91.62)	Dummy with a value of one if worked 27-39 weeks in 1959 (Variable 40)
-768.4 (80.15)	Dummy with a value of one if worked 40-47 weeks in 1959 (Variable 41)
-93.80 (95.34)	Dummy with a value of one if worked 48-50 weeks in 1959 (Variable 42)

$R^2 = .3421$

A large proportion of the personal characteristics are significantly related to Y , and many that are not have the expected signs and roughly the expected values (e.g., the time- and weeks-worked variables number 4, 35, 36, 38, and 42). A few of the coefficients have unexpected signs. One wonders why migration from distant cities should have a negative effect on earnings or why second-generation Americans should do better than those who are native-born of native parents. Perhaps the first effects lack of seniority or incomplete knowledge of employment opportunities and the second is a partial proxy for prolonged urban residence.

A more serious problem is that the line of causation between earnings and personal characteristics may be obscured. The positive effect of mobility from nearby urban residences may mean that more mobile persons have better opportunities or it may mean that the better paid more often moved to the suburbs during 1955-60. Again, the low earnings of persons who are not the main sources of support in their families may reflect a lower productivity of part-time workers, but a worker with very low earnings is apt to fall into this category almost by definition. However, when this regression was repeated with variables 26, 29, 30, and 32 excluded, the signs and statistical significance of the coefficients for the industry variables did not change.

Once the personal characteristics are introduced, the coefficients relating Y to U and CCR drop to nonsignificance. Table 4 shows estimated values of Y with the same values of CCR and U used in Tables 2 and 3,

TABLE 4—COMPUTED VALUES OF Y WITH GIVEN VALUES OF CCR AND U ASSUMING ZERO VALUES FOR ALL DUMMY VARIABLES AND MEAN VALUES FOR ALL OTHER VARIABLES

	Values of U	
	50	90
Value of 20	5165	5488
CCR 60	5314	5747

assigning zero to all dummy variables and mean values to all others. In other words, Table 4 illustrates the effects of concentration and unionization on the earnings of urban, white males with high school diplomas living in the Northeast who worked 51-52 weeks in 1959 and 40 hours in a nondurable-goods industry "last week" (April, 1960) and had mean values for age, family size, and the various industry characteristics. Concentration increases the earnings of such workers by only 3 to 5 per cent, and unionization increases their earnings by 6-8 per cent. When the same regression is run without the interaction variable ($U \cdot CCR$), a 40 point increase in U increases Y by 8 per cent and a 40 point increase in CCR increases Y by 5 per cent. The coefficient for U becomes highly significant ($t=5.0$) when $U \cdot CCR$ is dropped, but the coefficient for CCR is barely so ($t=2.1$). The implication seems to be that firms in concentrated industries do pay their employees more, but that they get higher "quality" labor in the bargain. The incomes won by unions for their members more clearly exceed what those workers would earn in their best alternative employments.

Most other industry characteristics drop to nonsignificance when

personal characteristics are introduced, and two of the remaining significant coefficients have unexpected signs.⁸ This is partly due to measurement errors. While concentration and important elements of union power are correctly measured on an industry-wide basis, employer size should ideally be measured on a personal basis, and employment growth on a SMSA-industry basis. However, the decline in the effect of industry characteristics as personal characteristics are introduced is consistent with labor market theory. Employers who, for any reasons, are in special positions which lead them to pay exceptional wages might be expected to get exceptional labor in the bargain.

The number of weeks and hours worked is understandably among the most important of personal characteristics in determining earnings. Leaving out all other personal characteristics, the equation becomes:

$$\begin{aligned}
 (4) \quad Y = & 2736 + \text{variables } 33-42 + 9.162CCR \\
 & (324.3) \qquad\qquad\qquad (8.420) \\
 & + 8.961U + .04811U \cdot CCR + 2.167G + 2.619L - 261.6D \\
 & (4.411) \quad (.1154) \qquad\qquad (.8403) \quad (1.771) \quad (76.23) \\
 & + 7.222M + 8.551Sk \qquad R^2 = .2203 \\
 & (2.567) \quad (2.973)
 \end{aligned}$$

The time variables reduce the effect of concentration, growth, employer size, and durability by about half compared with the equation (2) where only industry characteristics were used. The effects of unionization and the sex composition of the industrial labor force are roughly unchanged. The effects of concentration and unionization on earnings as other variables are introduced are summarized in Table 5. The time variables reduce the effect of concentration sharply but enhance the effect of unionization, if anything.⁹

⁸ Perhaps the time and weeks worked as reported in the Census do not identify the full effect of 1959 unemployment on earnings in durable-goods industries, or it may be that the often-observed high earnings in durables are due wholly to the unionization, concentration, employer size, or skill and sex mix in those industries. Another regression using average hourly earnings (from *Employment and Earnings*) also yielded a significant negative effect of durability when other industry variables were considered.

⁹ The results of this analysis hold in spite of several possible revisions in the sample or the model. The effects of CCR and U are both significantly positive when taken by themselves or with an interaction term whether we (1) eliminate apprentices (occupations 601-630) from the sample; (2) eliminate construction and mining (industries 126-196) from the sample; and/or (3) use estimated average hourly earnings as the dependent variable. The introduction of industry characteristics weakens but usually does not remove the effect of CCR on earnings. The introduction of only a few personal characteristics (age, race, and Southern and rural residences) does eliminate the effect of concentration in most cases. On the other hand, these revisions enhance the effect of U even when all the personal characteristics in equation (4) are included. Coefficients for these alternative samples and income variables are shown in the appendix available from the author.

TABLE 5—PERCENTAGE INCREASES IN ANNUAL EARNINGS WITH INDICATED INCREASES IN *CCR* AND *U* TAKING DIFFERENT VARIABLES INTO ACCOUNT

	Effect of Increase in <i>CCR</i> from 20 to 60		Effect of Increase in <i>U</i> from 50 to 90	
	if <i>U</i> is 50	if <i>U</i> is 90	If <i>CCR</i> is 20	if <i>CCR</i> is 60
Using Only <i>CCR</i> and <i>U</i>	33.4%	12.6%	15.9%	-2.2%
Using Other Industry Characteristics	15.5	10.6	8.6	3.9
Using Industry and Time Variables	10.0	10.7	8.6	9.3
Using Industry, Time, and Other Personal Variables	2.9	4.7	6.3	8.1

Concentration has less effect on the price of labor than on total earnings. This implies that, even if the earnings of labor in concentrated industries do contain an element of monopoly rent, the allocative effect is small. High earnings due to more time worked do not mean misallocation of resources, as high wage rates uncompensated by superior "quality" of labor might. The effect of unionization on earnings, on the other hand, seems to operate through wage rates rather than time worked, implying that resource misallocation would occur to the extent that high earnings in unionized industries do not simply reflect personal characteristics.

Time variables are in part proxies for other personal variables. Table 6 shows the distribution of various personal and industry characteristics by the number of weeks worked in 1959. The persons with short periods of employment were younger, more poorly educated, more likely to be currently in school, more likely to live in the South or in rural areas, and the more likely to have recently moved from a rural residence or from a distant SMSA. They were particularly likely to work short hours and to be a secondary source of family income. They were employed more often in slowly growing industries with small plants. In other words, short-time employment was not distributed randomly. It was most noticeable among the less-desirable employees, and as a result, the effect of time variables on earnings is at least partially due to the "quality" of labor involved.

IV. Regression Results for Other Occupation-Sex Groups

The results spelled out in detail for male operatives in manufacturing, construction, and mining in Part III are similar to those found for some but not all of the other populations studied.¹⁰ The coefficient for *CCR*

¹⁰ Coefficients for *CCR*, *U*, and *U · CCR* for all occupations and industries studied are included in the statistical appendix which is available on request.

TABLE 6—CHARACTERISTICS OF MALE OPERATIVES AND KINDRED WORKERS BY NUMBER OF WEEKS WORKED IN 1959

alone is always positive and almost always significantly so when no other variables are used. It remains positive in all cases except typists and retains its significance in most cases when *U* is introduced.

Table 7 summarizes the effects of concentration and unionization on *Y* when only *CCR*, *U*, *U·CCR* are used. The great majority of cases are consistent with the monopoly-wage hypothesis. The effects of *CCR* and *U* on *Y* are statistically significant for most male production workers. The only occupations that are unequivocally inconsistent with the monopoly-wage hypothesis are clerical workers when regulated indus-

servations in a range where *U* has a negative marginal effect. None of the coefficients that result in these equivocal cases is statistically significant.

The introduction of industry and personal characteristics changes the

findings sharply once more.¹² Table 8 classifies occupations by their degree of support for the "monopoly wage" hypothesis when all these other variables are used. Concentration now has a negative marginal effect on earnings over some range for most occupations, and the over-all effect of concentration is negative in as many cases as it is positive. The effect of unionism is more consistently positive. The positive effect of concentration and unionization on earnings seems to hold up best in the case of "craftsmen," perhaps because of greater power of the union there.

One intriguing result is the *negative* effect of concentration and unionization on the incomes of female clerical workers. Their earnings are increased if both *CCR* and *U* are high, but concentrated nonunion industries or unconcentrated, unionized industries seem to pay low clerical incomes. The high *CCR*-low *U* industries are mainly rapidly growing "high brow" industries (drugs, professional equipment and supplies, office, computing and accounting machines, photographic equipment and supplies, and at the borderline, miscellaneous chemicals). A possible explanation is that these industries must (and can) pay high wages to keep their production workers from organizing, but they face little such threat with their female clerical workers. The high *U*-low *CCR* industries are such fields as construction, trucking, coal mining, and beverages. Unions in such industries often organize the major occupations involved on an interfirm basis. They may not be much concerned with the pay scale of clerical help outside their membership. Indeed, to the extent that they secure high wages for the male production workers they represent, they may actually depress the demand for and, therefore, the price of complementary services such as those of female clerical workers. These suggested reasons for the apparent "exploitation" of clerical help in certain industries is blatant after-the-fact reasoning. We make no claim to have tested this "exploitation" hypothesis as we have the monopoly-wage hypothesis.

V. Conclusions

This paper examined two forms of the monopoly-wage hypothesis: (1) that concentrated industries pay high incomes for given occupations, and (2) that these incomes exceed the alternative costs of the labor involved. The first hypothesis holds up well, as it has in previous studies. The relationship is strongest for male production workers where the threat of unionization is undoubtedly greatest. Moreover, the interac-

¹² The same personal characteristics were used for each occupation as for operatives and kindred workers except that two more education dummies (for 4 years of college and 5 or more years of college) were introduced in the cases of "mechanical engineers" and "managers, officials, and proprietors, N.E.C."

tion between concentration and unionism most commonly has a negative effect for such workers. Both results give support to the notion that it is unionism or the threat of unionism that produces high wages in concentrated industries.

The second hypothesis should apparently be rejected. Once personal characteristics are introduced, the relationship between concentration and earnings is no longer significant and is negative about as often as it is positive. The monopolistic industries do get superior "quality" for the incomes they offer. Moreover, a substantial portion of the relationship between the earnings of labor in concentrated industries and their quality is due to a relationship of both variables with the number of weeks worked. The laborers in concentrated industries seem to receive no more for their services than they might in alternative employments for persons with similar personal characteristics. Their earnings contain little or no monopoly rent.

This does not necessarily imply that no misallocation results from high-wage payments in concentrated industries. Labor "quality" in this study includes such personal characteristics as race, which may be quite irrelevant to the objectively evaluated productivity of the laborer involved. It has been suggested that firms with monopoly power use part of their "profits" to hire congenial or socially acceptable employees [2], an option not available to employers subject to more stringent competitive pressures. If so, the earnings of labor in monopolistic industries may still exceed its marginal-revenue product, even though they apparently approximate the value of its alternative product.

The conclusion with respect to the effect of unionism on labor earnings is more equivocal than the results for concentration. The relationship between unionism and earnings does not decline greatly when personal characteristics are introduced for nonregulated industries. Unions that organize their entire jurisdictions seemed to raise earnings by 7 to 8 per cent for craftsmen and 6 to 8 per cent for operatives, compared with poorly organized industries. The relationship between unionism and earnings is often nonsignificant after personal characteristics are introduced, but this may well be the result of measurement errors. U was certainly the most difficult variable to estimate in this study. It has been claimed that the BLS *Industry Wage Surveys* overstate the extent of contract coverage because small employers are underrepresented. If this is correct, some of the effect of differing degrees of unionization may actually be included in the coefficients for the establishment-size variable instead of the coefficient for U . Finally, the only effect of unionism accounted for in this paper is its industry-wide impact. Differences within an industry between persons covered by collective bargaining contracts and those not covered had to be ignored. All of these consid-

erations seem to point toward an understatement of the effect of unionism on earnings.

A possible case of misallocation due to the effects of concentration and unionism on earnings is the particularly low income of female clerical workers in concentrated *or* unionized industries (but not in concentrated *and* unionized industries). Some sort of "monopsonistic exploitation" hypothesis may apply here. Little can be claimed for this hypothesis, however, since, unlike the monopoly- and union-wage hypotheses, it was not developed in advance of the empirical study.

The effects of most industry characteristics are nonsignificant and often of unexpected signs after personal characteristics are introduced. In general, employers who for any reason pay high salaries receive "superior" labor in the bargain. The general picture is one of fairly efficiently working labor markets, even where substantial monopoly may exist.

All of the conclusions of this paper are necessarily tentative because the indexes of concentration used are imperfect, because industry definitions are arbitrary, because weights used in combining markets to match Census industries are arbitrary, and because the Census places some persons in the wrong industries. It might be argued that the nonsignificance of concentration as a factor in income determination once personal variables are introduced is due merely to measurement errors. On the other hand, the significant results before personal characteristics are introduced suggest that much of the effect of monopoly power has in fact been identified, and that at least this identified portion is almost entirely accounted for by personal characteristics. Moreover, a great number of personal characteristics could not be adequately measured, either. Such obviously pertinent variables as health, intelligence, appearance, strength, manual dexterity, sobriety, and responsibility could only be approximated by distant proxies such as age, sex, education, and family status if they were included at all. If the high-wage employers were as successful at hiring and retaining intelligent and responsible persons as they were in hiring educated ones, it would seem as likely that the residual effects of concentration are exaggerated in this study as that they have been missed.

THE EFFECT OF INCOME ON DELINQUENCY

By BELTON M. FLEISHER*

Recent government policy is evidence of considerable public interest in the relationship of young people to the labor market. Delinquency problems arise in this context because decisions to engage in illegitimate activity seem interconnected with decisions about schooling, labor force participation, and even occupational choice. Thus a study of factors affecting delinquency is of interest not only to criminologists and to crime prevention agencies, but to all those concerned with the allocation of youth's time among alternative pursuits.

This study is an attempt to discover whether low income is a cause of juvenile delinquency, and if so, to present evidence of its importance. Economists have often investigated relationships between income and expenditures—Engel's being perhaps the earliest well-known work of this type; in addition they have recently begun studying quantitatively the effects of income on other behavior. Two novel analyses of income-behavior relationships are the recent studies of Becker on fertility and of Mincer on the labor force participation of married women [1] [7]. So, while my subject matter may seem strange to economists, it is not really deviant from an important tradition involving the application of economic analysis to a rather wide variety of social phenomena.

The literature on delinquency contains a wide range of estimates (both negative and positive) of the effect of income. However, there is little consensus regarding their meaning. This lack of consensus is largely due to the absence of an accepted theoretical framework for analyzing delinquency and to a lack of agreement about which empirical observations best represent the analytical concepts that have been employed. I think the approach to the problem employed in this study can eventually promote considerable progress toward an understanding of the effect of economic conditions upon delinquent behavior.

* The author is assistant professor of economics at Ohio State University. Research for this paper was carried out under United States Department of Health, Education and Welfare Grant No. 62216 at the University of Chicago. Professor Morris Janowitz, Department of Sociology, University of Chicago, originally interested the author in the subject matter of the paper. The author has received substantial benefits from the comments of H. Gregg Lewis. The paper has also benefited from comments of Margaret G. Reid and from presentation to the Research Group in Labor Economics of the University of Chicago. The author bears sole responsibility for any errors.

I. *An Economist's View of Delinquency*

Most studies of the effect of income on behavior purport to present estimates of demand or supply functions, and this study is no exception because it is an attempt to estimate a net causal relationship running from income to delinquent behavior. The economist's ordinary tools of supply and demand appear useful in constructing a model for the empirical investigation of delinquency. I shall use the concept of demand to mean a causal relationship between economic and other characteristics of persons on the one hand and their tendencies to commit delinquent acts on the other. But the number of delinquent acts committed should depend also on the number or value of delinquency opportunities. I assume that the supply of delinquency opportunities depends on the economic and social characteristics of the environment. I further assume the interaction of these two forces—the propensity to be delinquent and the opportunities available—determines the number of delinquent acts actually committed. The use of an economist's tools to analyze delinquency does not in any way presuppose that "economic" variables such as income are the most important factors determining delinquency rates. It still remains to estimate their importance in the context of a model which allows us to view separately the possible effects of income, opportunities, and other factors.

The question of just what constitutes these "other" factors is of crucial importance. Intuitively one believes that personality traits and family characteristics must play an important role in determining delinquent behavior within rather broad economic and social constraints. It is these to which I refer in the concept of "taste for delinquency." Insofar as these tastes are correlated with incomes, it is necessary to specify them correctly so that their influence is not included in the estimates of the effect of income, and vice versa. Also at the intuitive level, one suspects that those personal traits which cause some individuals, other things the same, to earn more than others—stability, industriousness, etc.—also contribute to low delinquency rates. It therefore appears likely that taste for delinquency and income levels will be rather highly correlated.¹

¹ It is perhaps risky for someone trained in economics to try to explain what has been going on in another discipline, such as sociology. However, it is desirable to attempt to relate the "economist's view" of delinquency to the "sociologist's view." In my opinion, the concept of taste is closely related to sociological concepts such as "anomie." When sociologists argue the relative merits of "commitment to the existing social structure" vs. "opportunities" or "material well-being" as variables explaining delinquency, they refer to questions which I hope to be able to answer at least partially with a model taking into explicit consideration both tastes and economic variables. The problem that criminologists and sociologists have not solved, and for which it will become apparent that I have not provided the definitive solution, is the identification of those observable phenomena which

While tastes are undoubtedly important determinants of legitimate vs. illegitimate behavior, it is intuitively appealing, and casual inspection leads one to suspect, that economic factors are also an important cause of delinquency. The principal theoretical reason for believing that low income increases the tendency to commit crime is that it raises the relative cost of engaging in legitimate activity. In the first place, youngsters probably view their families' income as an index of their own long-run legitimate earning possibilities. Thus, so long as there is not substantial positive covariation between the expected returns to legitimate and illegitimate activity, individuals with low incomes (or whose parents have low incomes) probably expect relatively large payoffs for committing delinquent acts. To such individuals, the probable cost of getting caught is relatively low, since because they view their legitimate lifetime earning prospects dismally they may expect to lose relatively little earning potential by acquiring criminal records; furthermore if legitimate earnings are low, the opportunity cost of time actually spent in delinquent activity, or in jail, is also low. A related possible effect of income on delinquency is due to the lifetime pattern of income. Since most legitimate careers entail lower earnings during their earlier stages (especially during formal schooling) than in their later stages, youngsters who can rely upon little help from parents or other family members in providing desired goods and services may well be tempted to engage in illegitimate activities on a "part-time" basis.

As stated above, casual observation also leads one to suspect that poverty causes high delinquency rates. Particularly within cities, it has long been observed that areas of low incomes, high unemployment, and the like are the areas of highest delinquency rates.² It is also true that a disproportionately large number of serious crimes for which youth are arrested are crimes against property. In 1961, for instance, 93 per cent of the serious arrests of people aged less than 25 were for the crimes of robbery, burglary, larceny, and auto theft [4, p. 544]. Although this age group constituted only 43 per cent of the 1960 population of the United States, in 1961 it accounted for almost 90 per cent of the arrests for auto theft and over 60 per cent of arrests for the remaining property crimes [4, p. 544].³

While incomes are conceptually negatively related to the cost of en-

are the operational equivalents of conceptual tastes for delinquency. In statistical jargon, we are not reasonably certain how to specify properly a model of delinquency. Consequently all interpretations of the results of empirical investigations are weakened by our not knowing whether we are observing the effects of the variable we conceive as relating to delinquency or whether we are observing the effects of misspecification of the model of delinquency.

² A classic study is [8].

³ I think it is advisable to point out that it is by no means inconsistent with the above

gaging in delinquent activity, they are positively related to the expected gains. This is true of crimes against property, at least, which constitute a disproportionately large number of the delinquent acts of youth. The greater the income or wealth of potential victims, the greater will be the expected value of theft. Consequently, income has two conceptual influences on delinquency which operate in opposite directions, although they are not necessarily equal in strength. Thus it is desirable to attempt to estimate these influences separately. In terms of an economist's view of delinquency, the expected negative relation between income and delinquency can be expressed as a demand relationship, and the expected positive relation as supply.

II. *A Simple Model of Delinquency*

Variables Employed

I present now the list of variables employed in the empirical investigation. I shall discuss what theoretical concepts the variables are thought to represent, how they fit into a simple model of delinquency, and some biases that may be included in their estimated effects.

1. The dependent variables employed are not, by necessity, actual juvenile crimes or crime rates. Since it is necessary to know the ages of offenders in order to identify crimes of youth, arrest and court-appearance data are used in forming dependent variables. It is generally thought to be a fault of arrest and court data that the probability of one's appearing in these statistics, given one's actual offense record, is negatively correlated with economic and social standing. Thus the use of arrest and court data may impart a negative bias to the estimated (demand) effect of income on delinquency. Since this economic or social bias is thought to be stronger, the farther removed is the measure of crime from the actual commission of the crime, arrest data may yield more reliable estimates of the income effect than do court-appearance data. The influence of social standing on the number of reported arrests and court appearances is probably greatest within police

discussion of the relationship between economic factors and delinquency rates to observe that incomes and crimes of violence are also negatively correlated. Insofar as violent activity has entertainment value, or whatever, to those who engage in it, the economic cost of such activity in terms of the penalties associated with apprehension will be low if youths expect only minor effects on their lifetime earnings. A youngster who aspires to become a lawyer cannot afford to have a police record for assault or rape. However, such a record would probably be relatively unimportant to a potential manual laborer. It is also conceivable that any pleasure derived from violent crimes may be a substitute for market goods and services. They may also be complements, however, as one supposes that higher incomes are associated with increased consumption of alcoholic beverages, and through this medium may be positively associated with crimes of violence. Finally, one should not ignore the possibility that crimes of violence and property crimes may be complements in the economic sense.

and court jurisdictions, as it is probably relative levels of income and social influence that are important.

I think one must beware of exaggerating the importance of socioeconomic bias in arrest and court-appearance data. Undoubtedly one of the causes of bias is that the influence of parents of relatively high socioeconomic standing on the behavior of their children is generally thought to lead toward legitimate behavior. Thus, the probability of a child's being punished at home on account of a complaint from the police is thought to be smaller, the lower the social or economic standing of the family from which he comes. It is therefore probable that the low-status child who gets into trouble will commit more crimes in the future if he is not brought to justice formally when he is apprehended. I do not mean to pass judgment at this point on the efficacy of our methods of dealing officially with juvenile offenders; I merely wish to point out that biases in arrest and court-appearance data may well reflect real differences in the tendencies toward delinquency of different segments of the population.

The actual dependent variables used in this study depend upon the sample from which they were taken. They are:

Y_{cc} , the number of court appearances of males, aged 12 through 16 years, during the years of 1958-61, for the census tract communities in the city of Chicago. (Census tract communities are aggregates of census tracts which purport to represent useful subdivisions of the city into areas of rather stable community structure.)⁴ The number of appearances is expressed as an annual average number, per thousand males aged 12 through 16.

Y_{cs} , the same as Y_{cc} for 45 suburbs of Chicago in Cook County with populations in excess of 10,000. These data were provided by Henry D. McKay of the State of Illinois Institute for Juvenile Research.

Y_{usp} , the number of arrests of males, aged less than 25 years, for crimes of robbery, burglary, larceny, and auto theft, in each of 101 cities of the United States with populations greater than 25,000. The number is expressed as the rate per thousand males less than 25 years of age. Information is available for most of the cities for the years 1960, 1961, and 1962, but not for all of them. The data are expressed as annual average rates.⁵

Y_{usv} , the same as Y_{usp} , except that the arrests are for crimes of

⁴ See [5]. The Chicago delinquency and other variables are taken from [5].

⁵ These data are based on information provided by the United States Federal Bureau of Investigation. They are not published, as the FBI assures reporting cities of the anonymity of the information provided by them. While they do not represent an exhaustive list of all U.S. cities with more than 25,000 population, they do represent all size classes in this range.

violence, namely homicide, rape, and assault.

2. Although a number of income variables were experimented with in this study, only three of them are used in the results reported here. Two variables represent income as usually conceived.

MEINC2 is the mean family income of the second lowest quartile of families which receive income. This variable is intended to stand for the economic level of a community as it affects the tendency to commit delinquent acts.

MEINC4 is the mean income of the highest quartile of families. This variable represents an attempt to measure the payoff for certain kinds of delinquent behavior. These two measures of income are generally used together in the regressions, as follows:

$$(1) \quad Y = a + b \text{ MEINC2} + c \text{ MEINC4} + \dots$$

Equation (1) can be rewritten by adding and subtracting $c \text{ MEINC2}$ to the right-hand side, yielding

$$(2) \quad Y = a + b \text{ MEINC2} + c \text{ MEINC4} + c \text{ MEINC2} - c \text{ MEINC2} + \dots$$

When equation (2) is rearranged, we find that (1) is the equivalent of

$$(3) \quad Y = a + (b + c) \text{ MEINC2} + c(\text{MEINC4} - \text{MEINC2}) + \dots$$

Thus, the sum of the coefficients of the two income variables yields an estimate of the effect of family income on delinquency. The coefficient of the fourth quartile yields an estimate of the income dispersion on delinquency. The sum $(b + c)$ can be thought of as the demand relation between income and delinquency, and the coefficient c can be thought of as the supply relation. Other measures of family income and dispersion yielded regression results so close to those obtained using equation (3) that it does not seem worthwhile to present them.

The income data are all taken from the 1960 Census of Population and refer, of course, to incomes during the calendar year 1959.⁶

3. In attempting to estimate the effect of income on delinquency, it is important to consider the effects of both normal family incomes and deviations from normal due to unemployment. Both normal incomes and deviations from normal may affect delinquency, but the effect may be different.

UNEMMC is the male civilian unemployment rate taken from the 1960 Census of Population.

4. Four variables are employed to represent tastes. *SPDVFM* is the

⁶ Mean income of the lowest quartile is not employed, as it is most likely to be influenced by family structure and other characteristics of the samples which are highly correlated with taste. Since low-income groups tend to be more delinquent than other groups, *MEINC 2* is probably a good measure of the economic opportunities of potential delinquents.

proportion of females over 14 years of age who are separated or divorced. This is supposed to reflect the proportion of broken families in the community. I shall refer to it as the family-structure variable. There are several means by which family structure may influence delinquency. An obvious means is that families with only female heads tend to have lower incomes (by about 50 per cent) than do families with both male and female heads. However, the multiple regression technique, which estimates the effects of income and family structure simultaneously, is an attempt to remove the income component from the estimated effect of family structure on delinquency. Another means by which family structure may affect delinquent behavior is through parental supervision and guidance. This works in two ways, both of which are related to the fact that children in broken families usually live with only their mothers as adult family members. The first is that the mother is likely to have to supplement the family's income with her own earnings if the father is not present. This means that she has less time to supervise the activities of her children. Secondly, it is a widely held belief that boys (who constitute the bulk of delinquents and with whose behavior we are exclusively concerned in this paper) learn about the economic facts of life primarily through their relationship with the father and his connection with the economic system. To the extent that legitimate endeavor requires a longer time horizon—a clear view of relatively distant payoffs—than does illegitimate behavior, absence of a male family head probably works in favor of delinquency. Of course, the male family head probably helps reduce delinquency by participating in the pure supervisory role, along with the female head.

It is important to consider whether, supervisory roles and labor market connections aside, the family-structure variable has still an additional influence on delinquency. If this variable truly reflects what I have referred to as the taste for delinquency, it will affect behavior not only through the means discussed in the preceding paragraph, but also because, given the amount of supervision, etc., parents are able to provide their children, the attitudes of broken families will be oriented less toward what is generally regarded as legitimate behavior and more toward delinquent behavior. If the family-structure variable does reflect such a taste factor it may serve the purpose of holding tastes constant so that the true income effect may be estimated. The supervision and market connection phenomena are analogous to tastes in this context and are additional reasons for including the family-structure variable in the regression analysis.

But there is an important way in which family structure may be related to delinquency which would be a reason for excluding it from the

regression analysis. Suppose that causation runs from delinquency to divorce, rather than vice versa. For instance, consider the possibility that delinquency is partly caused by economic variables, which are included in the regression analysis. Suppose also that delinquent populations tend to have higher divorce rates than others. Then by putting the family-structure variable in the regression we may rob the economic variables of their effects; which variable "wins" may depend principally upon which has the least serious errors of measurement.⁷ I can do no more than point out this possible source of error in interpreting the regression results and then go on; without a well-developed theoretical model of delinquency and a great deal of testing, the probability is always high that empirical work will be hampered by doubts regarding specification.

MOBILR is the proportion of the population over five years of age that lived somewhere other than the community of current residence five years previous to the 1960 census. The variable is an attempt to capture, and to hold constant, the effect on delinquent behavior of residing in a strange community. Presumably new residents are less likely to observe the established codes of behavior of the community than old residents. While the mobility variable may also reflect any temporary losses of income associated with moving, this effect should be mostly eliminated by the presence of the income variables in the regression equations. The expected influence of mobility is to increase delinquency, except for one possibility.

If a large proportion of a community's recent in-migrants arrived only in the year before the census, then the income variable for these people will in part reflect income of a previous job which, if the in-migrants are moving toward improved economic opportunities, may be lower than current income. In this case, the mobility variable may pick up the tendency of current income to be higher than measured income; this influence on delinquency rates should be negative.

⁷ It is possible, but factually less appropriate, to apply this same argument to the income variable. It could be held, for instance, that delinquent populations have lower legitimate earnings than do other populations, and that this is reflected in reported family incomes. However, the income variables used reflect income of the whole community; it seems likely that more conventional economic factors outweigh any effects of delinquency on the measured family incomes of communities. This, I think, is even true of the Chicago census tract communities, which are likely to be more homogeneous than the suburbs or 101 cities. In any event I would argue that the use of the taste variables in the regressions tends to hold constant the effect of delinquency on earnings.

In the extreme case that both the income and taste variables are "caused" by delinquency, we are in the unfortunate situation of not having a properly specified model of delinquency at all. We are merely doing correlation analysis in the most literal sense.

I feel that it is likely that some element of reverse causation is present and confounds the regression results presented here. However, I think the importance of this is greatest for the family-structure variable and of negligible importance for the income variables.

NWHITE is the proportion of the population that is nonwhite. Its use is an attempt to pick up any taste factors, associated with race, which are not reflected in the other taste variables. One hardly need mention that the racial composition of a community is correlated with its income and family characteristics.

NSDUMM is a regional dummy variable, equal to one for Southern cities and equal to zero for all other cities. It is employed only in the 101 cities analysis.

The independent variables and their symbols are listed in Table 1.

The source of all variables not specified elsewhere is the 1960 Census of Population.

III. Results of the Regression Analysis

Since the delinquency rate is conceptually bounded by zero and one thousand, it is not unlikely that a nonlinear relationship exists between

List of independent variables employed in the regressions.

MEINC 2 Mean income of the second lowest quartile of income recipients (1959).

MEINC 4 Mean income of the highest quartile of income recipients (1959).

UNEMMC Male civilian unemployment rate (1960).

NWHITE Proportion of the population that is nonwhite (1960).

MOBILR Proportion of population of five-year-olds that lived in another county in 1955 (1960).

SPDVFM Proportion of females over 14 who are separated or divorced (1960).

NSDUMM Regional dummy variable equal to one for Southern cities, zero otherwise.

the rate and some of its causes. Also, it has been suggested that the influence of incomes on delinquency will be greater in the presence of a high proportion of separation and divorce. That is to say, the response of potential delinquents to economic incentives may be greater in communities that have high tastes for delinquency than in communities with strong tendencies toward legitimate behavior.

Thus, for purposes of estimating the effects of the income and taste variables, the two largest samples (101 cities and Chicago communities) were divided into three subgroups of approximately equal size, according to the values of the family-structure variable. The observations in a high subgroup have the highest proportions of separated and divorced females, and so on. The regressions were estimated using both the entire samples and the subgroups. The division into subgroups is an attempt to capture any effects of nonlinearity in the true relationships and/or interactions between variables and effects that may exist. It is also a method of holding constant tastes as reflected in the family-structure variable. I think it is realistic to consider the Chicago suburbs as corresponding to either of the lowest subgroups of the two other samples. Table 1 presents some of the sample statistics for the samples and their subgroups. There are substantial differences among the subgroups in the level and variance of the family-structure variable. There are also notable differences in the levels of delinquency and income.

The regression results are shown in Tables 2 through 6. Most of the regression coefficients are large enough to be interesting from the economic or sociological point of view, and most of the coefficients of economic variables are statistically significant.* If one is interested in comparing the size of the effects of the variables included in the regressions, the elasticities, which are calculated at the mean values of the variables, are of interest. These are estimates of the percentage change in the dependent variable which occurs when there is a 1 per cent change in the independent variable.

Table 2 shows the regression results for the 101 cities sample and subgroups. Examination of the results of the regressions based on the entire 101 cities sample shows that adding the family structure variable to the regression has a substantial effect on the multiple R^2 and on

*I think it is appropriate to apply a one-tailed test of significance to the regression estimates. With 19 degrees of freedom (the smallest number for any of the regressions) a t -ratio of .86 indicates statistical significance at the 20 per cent level.

A one-tailed significance test seems appropriate because of the a priori considerations which suggest the signs of the regression coefficients. While a 20 per cent level of significance is high by some standards, I believe it is not inappropriate, considering the desirability of reducing both "type I" and "type II" errors. The reader is of course free to establish whatever criteria for statistical significance he chooses.

the estimated coefficients of the other variables. The results of regressions including the family-structure variable imply that there is a non-negligible negative effect of income on delinquency, but they fail to show the predicted effect of the income dispersion, or supply variable. Removing mean income of the highest quartile (*MEINC 4*) from the regression results in an increase in the statistical significance of mean income of the second lowest quartile (*MEINC 2*) and in the size of the income (demand) effect.⁹ The estimated effect and statistical significance of unemployment are small, as are the estimated effects of the proportion nonwhite (*NWHITE*) and mobility (*MOBILR*). The

⁹This is true even when the coefficient and standard error of *MEINC 2* estimated alone are compared with the sum of the coefficients of *MEINC 2* and *MEINC 4* and the standard error of the sum.

North-South dummy variable (*NSDUMM*) coefficient indicates that, other things the same, delinquency tends to be lower in the South than it is in the North.

Rather different inferences can be drawn when the subgroup results are examined. Since a priori considerations suggest that stratifying the samples will improve the specification of the model, I shall base further interpretation of the results primarily on the stratified regressions. The highest subgroup yields large, significant estimates of both the supply and demand aspects of income. The family structure variable and *NSDUMM* have estimated effects absolutely larger than those in the aggregate sample. The estimated effects of *MOBILR* and *NWHITE* are negative. The lower groups yield estimated effects of income dispersion similar to the combined sample. The estimated effect of income declines in value and in statistical significance as one moves from high to low subgroups.¹⁰

Examination of the Chicago communities reveals a striking

¹⁰ Table 3 shows the regression results for the 101 cities' property crimes, individuals aged 17 and under. Since the coefficient of *MEINC 4* was insignificant, I have shown only the results with *MEINC 4* eliminated from the regressions. This regression may be compared with regression number 3 in Table 2. The principal difference is that the regression for the younger age group has a lower R^2 , and the coefficients are less significant statistically. A possible interpretation is that the variables included in the regressions affect delinquency of both age groups in a similar manner; however, the response of the younger age group is less consistent.

Table 4 shows the regression results for the 101 cities subgroups violence crimes, individuals aged 24 and under. The violence-crimes regression for the 101 cities sample, individuals aged 17 and under, is reported in Table 3. The statistical significance of economic factors is lower in the violence-crimes regressions than in those for property crimes; the coefficient sometimes have the "wrong" signs as well. This is evidence consistent with the hypothesis that the estimates of the income effects do not include the effects of tastes.

difference from the 101 cities; the estimated effect of *SPDVFM* is relatively small and tends to be insignificant. The estimated effect of income dispersion is positive in all subgroups, but highest in the medium. Similarly, the effect of income appears highest in absolute terms in the medium group. The statistical significance of both income variables is also highest there. Since the difference between the coefficients of the income variables in the two highest Chicago subgroups is small compared with the standard errors of either subgroup, it seems fair to conclude that the evidence of the Chicago subgroups does not contradict the 101 cities evidence that income effects are most pronounced in the highest subgroups. The estimated effect of unemployment is positive in all three subgroups. Its size is large, and the coefficients are statistically significant. The estimated effect of mobility in the Chicago subgroups is positive and significant, and the effect of racial composition appears to be negligible.

I now turn to the regressions based on the Chicago suburbs sample, once again drawing attention to the similarity between this sample and the lowest subgroups of the Chicago communities and 101 cities samples. The effect of income on delinquency appears negative. The estimated effect is much more sensitive than in the other samples to the covariation between the two income variables, and when *MEINC 4* is removed, the estimated effect is similar in significance to the lowest 101 cities subgroup.¹¹ It is smaller than the estimate in the lowest Chicago communities subgroup. The estimated effect of unemployment is both substantial and significant. The estimated effect of mobility is positive, but of low significance, and the effects of race and family structure appear to be negligible.

I think one can discern a general pattern of behavior that is reflected in these regression estimates. The over-all effect of income on delinquency appears to be negative and more pronounced among "delinquency prone" groups than among others. The negative effect of income on delinquency may be somewhat offset by the positive influence of income on the payoff for property crimes. The offsetting effect also appears to be most pronounced in the most-delinquent groups. Unemployment appears to be a cause of delinquent behavior, but the inter-subgroup pattern of the unemployment effect does not seem to be the same as the pattern of income effect. That is, there is no tendency for the high subgroups to exhibit an especially strong response to temporary deviations from normal incomes as measured by unemployment.

¹¹ The regression results in Table 4 show the effect of *MEINC 2* alone, *UNEMMC*, *NWHITE*, and *MOBILR* in the absence of *SPDVFM*. However, inclusion of *SPDVFM* appears to have only a negligible effect on the regression coefficients derived from this sample.

This study is mainly concerned with the effects of economic factors on delinquency, but it is interesting to note that holding economic and taste factors constant, the addition of a racial variable (*NWHITE*) adds almost nothing to the explanatory power of the regression model in any of the samples.

IV. Evaluation and Conclusion

Specification of the Model

In evaluating the results of these regressions, probably the most important question is whether the model has been correctly specified. In fact, there is not a great deal of evidence that it has. The erratic behavior of the family-structure variable is not strong evidence of its appropriateness in the regressions. Furthermore, *SPDVFM* is correlated

TABLE 7—101 COMMUNITIES

Dependent Variable <i>SPDVFM</i>				
Variable	Regression Coefficient	<i>t</i> -Ratio	Elasticity	Multiple <i>R</i> ²
<i>MEINC 2</i>	-.000010	-3.1	-.88	.38
<i>MEINC 4</i>	+.0000023	+2.9	+.53	
<i>UNEMMC</i>	+.30	+2.5	+.26	
<i>MOBILR</i>	+.070	+2.6	+.10	
<i>NSDUMM</i>	+.0076	+1.4		

with the income variables, *MOBILR* and *NSDUMM*, in much the same way as delinquency. Compare the regression results in Table 7 with those of Table 2 (Regression #1); the elasticities are similar, and the multiple *R*² is higher. Thus it is impossible to rule out the possibility that *SPDVFM* is either caused by delinquency or is so closely related as to be virtually the same phenomenon. While there is no suggestion at present regarding which alternate taste variable would improve the estimates, my experience with the effect of employing alternate taste variables indicates that there is little effect on the estimated income effects.¹² Thus, it is possible that, although we still cannot pro-

¹² The literature on delinquency contains a number of empirical studies in which alternate taste variables have been used. This is not to say that the writers of these studies used such terminology; I am imposing my own framework on what I think these authors were attempting to do. Three important studies were those of Lander for Baltimore [6], Bordua for Detroit [2], and Chilton for Indianapolis [3]. Variables which were used, I think, primarily to hold tastes constant were proportion nonwhite, proportion foreign-born, proportion of homes owner-occupied, proportion of homes substandard, and the proportion of unrelated individuals to families plus unrelated individuals. These studies never reported regression coefficients, but only partial correlation coefficients and/or beta

fess to know all the important variables that should be included in a model of delinquency, we nevertheless have obtained "reasonable" estimates of the effect of economic conditions.

The Effect of Income

Given the reliability of the estimates of the effect of economic conditions on delinquency, I should now like to explore some of their implications. To begin with, it appears that the effect of income on delinquency is not a small one. In extremely delinquent areas, a 1 per cent rise in incomes may well cause a 2.5 per cent decline in the rate of delinquency. The effect of income dispersion—the supply effect of income—probably operates only in very delinquent areas, and it is probably not large relative to the demand effect of income.

Remember that the estimated income effects are net of the effects of other variables in the regressions. If it is true, as seems likely, that family structure is a function of income, then changes in income not only will operate directly upon delinquency rates, but indirectly through family structure, as well. One must not be too mechanical in applying the indirect relationship to policy questions, however. It is unlikely that changes in income transfer payments, such as unemployment compensation, ADC payments, and the like, would have the same effect on family structure as would changes in the earning power of individuals—especially males. Nor would all the indirect income effects be desirable ones. Increased community income would probably attract in-migrants, and through this means rising incomes would probably cause delinquency to increase.

To illustrate the possible influence of economic conditions upon delinquency, consider the following simple example based on the regression estimates of the high 101 cities subgroup. Suppose that the average family income in this subgroup is raised by \$500 per year for all income classes. (The effect of the change in income of the first and third quartile is assumed to be reflected in the coefficients for the second and fourth.) The pure income effect on delinquency would be $(-.0093 + .0013) 500 = -4.00$, which is to say that the rate would fall by 4 arrests per thousand population, a reduction of somewhat more than 15 per cent of the average rate in the sample. Now suppose that the increase in income has an effect on family structure equivalent to one-half the estimated effect shown in Table 7. I assume only half, because

coefficients. Usually, variables explicitly representing incomes did not pass a conventional *t*-test for significance. However, I have performed regression analyses of the data for Detroit census tracts (1950) and for Indianapolis census tracts (1960; the Indianapolis data were provided by Roland Chilton). The effect of income appears similar in both the Indianapolis and Detroit samples; I virtually duplicated the Detroit study, obtaining an estimated income effect of $-.0018$ (elasticity = $-.50$), and a standard error of $.00091$.

income changes cannot be expected to change tastes for delinquency, but to operate on delinquency through family structure via the supervision and market connection effects. From Table 7, we can estimate that a \$500 increase in family income will cause a decline in the number of women over 14 who are separated or divorced of about 2.7 per thousand women. One-half of this effect times the estimated impact of family structure on delinquency would imply a decline in the delinquency rate of one. This is 25 per cent of the direct impact of income. In addition, I estimate that the delinquency rate will be reduced by still another one-half of 1 per cent because normal families have higher incomes than broken ones. These rough calculations indicate that a 10 per cent rise in income may be expected to reduce delinquency rates by between 15 and 20 per cent when the income change occurs in highly delinquent areas and is of the type that will reduce the number of broken families as well.

The Effect of Unemployment

The estimated elasticities of the unemployment-delinquency relationship are in general smaller than those of the effect of income. However, aside from the highest 101 cities subgroup estimate, they are all positive and between .05 and .60; this range includes most of the estimates from a previous time-series analysis of the effect of unemployment on delinquency [4]. There is no evidence that the effect of unemployment is higher in the high delinquency subgroups than in the low, as is the effect of income. One may only speculate at this point as to why this may be. Two possible explanations come to mind. One is that, in the groups which have high rates of separation and divorce, high unemployment substantially increases the amount of parental supervision. I think this is intuitively an unappealing explanation. For one thing, the high separation and divorce group probably has high tastes for delinquency; it is problematical whether increased parental supervision in such circumstances would do much to reduce delinquency rates. For another, it seems likely that family morale is low during periods of high unemployment and that parental discipline is not likely to be vigorous.

What seems a more plausible explanation arises from the correlation between family structure and income. Broken families occur more frequently among low-income groups than among high.¹³ There are two

¹³ This is not only because broken families usually have only one principal earner. It is also because broken families would have lower incomes, on the average, even with two principal earners. A rough indication that this is true is that the differences in mean incomes (as measured by *MEINC* 2) among the subgroups in Table 1 are considerably larger than can be explained by the hypothesis that the differences are solely due to differences in family structure, assuming that families with only female heads have incomes equal to one-half those of families with both male and female heads.

implications of this observation: (1) unemployment compensation is likely to be a more powerful offset to the effects of unemployment for low-income families because there are ceilings on unemployment benefits; (2) in the high subgroup families, unemployment is likely in part to constitute a permanent feature of earnings; this means that differences in unemployment among observations may not consistently reflect differences in deviations of actual income from normal income.¹⁴

It would be misleading, I feel, to conclude on the basis of the relatively low estimated elasticities of the relationship between unemployment and delinquency that unemployment is consequently a less important explanatory or policy variable than income. For instance, the speculations of the preceding paragraph (and the regression estimates) are consistent with a positive effect on delinquency of changes in the general level of unemployment, even for the high subgroups. Another important consideration is that the variation (as measured by the coefficient of variation) of unemployment rates is much higher than the variation of incomes. This is true in the samples used in this study, and I think it is true in general for these kinds of samples. Thus, to the extent that the "normal" variation of the variable is an index of the constraints within which policy-makers must operate, there is more scope for changing unemployment than for changing income levels directly. Perhaps the most important consideration is that social policy which permanently reduces unemployment will also raise normal levels of income, and reducing unemployment in high-delinquency areas will probably have relatively large effects on normal income levels. This is because unemployment rates in these areas are high to begin with and probably constitute part of the environment determining normal earnings; a 50 per cent reduction in unemployment rates in an area where nearly 10 per cent of the labor force is unemployed may raise average incomes by as much as 5 per cent (perhaps less if the chronically unemployed are less productive than other earners). In the light of the numerical example illustrating the income effect, such a reduction of the unemployment rate could possibly reduce the delinquency rate by 10 per cent.

Finally, while changes in incomes alone do not explain the behavior of delinquency over time, if one assumes an elasticity of the relationship between income and unemployment of .15 (which is consistent with the estimates presented in this paper and with those of a previous study of the relation between delinquency and unemployment over

¹⁴ Another possibility is that, since current income is being held constant in the regressions, residual unemployment among observations is therefore negatively correlated with permanent income. This could lead to a negative coefficient for unemployment if the permanent income effect were strong relative to the unemployment effect.

time)[4] one can "explain" about 15 per cent of the measured increase in juvenile delinquency from 1952 through 1960.¹⁵

EMBODIED PROGRESS, INVESTMENT, AND GROWTH

By H. A. JOHN GREEN*

The aggregate production function, despite its shortcomings, has been widely used in discussions of economic growth. Among the problems to which it has been applied are the identification of sources of increased productivity and the relationship between investment and growth. In connection with both problems the distinction between "embodied" and "disembodied" technical progress has achieved wide currency. In this paper, after a discussion of some of the properties of an aggregate production function and of "efficiency units," it will be argued that the concept of embodied progress has not received a precise definition. Three alternative interpretations of the concept are given; it is shown that on only one of these interpretations—a somewhat unorthodox one—is embodied progress directly relevant to the relationship between investment and growth.

I. *The Aggregate Production Function*

In a model which incorporates the aggregate production function:

$$(1) \quad Y = F(J, L, t)$$

each of the aggregates Y (gross output or income), J (capital), and L (labor), requires close examination. Gross output is composed, to consider only the first step in disaggregation, of consumption and gross investment. There are therefore two production functions:

$$(2) \quad C = F_C(J_C, L_C, t); \Delta J = F_I(J_I, L_I, t).$$

We make the following four common assumptions: (a) the production functions in (2) are homogeneous of degree one in capital and labor; (b) the amounts of capital employed in the two sectors may be *added* to obtain the total capital employed in the economy (and similarly for labor), so that

$$(3) \quad J = J_C + J_I; L = L_C + L_I;$$

(c) given totals of J and L are efficiently allocated between the two

* The author is professor of economics at the University of Toronto. In revising earlier drafts of this paper, he has benefited greatly from correspondence with Professor R. M. Solow, from discussions with Professor H. Rose, and from the comments of two referees.

sectors; (d) aggregate output Y is some function of the outputs of the two sectors:

$$(4) \quad Y = U(C, \Delta J, t)$$

with $\partial U/\partial C$ and $\partial U/\partial \Delta J$ both positive. Then it can be shown¹ that the aggregation implicit in equations (1)–(4) requires that at any given time t one of the sector production functions is simply a multiple of the other:

$$(5) \quad C = F(J_C, L_C, t); \Delta J = R(t) \cdot F(J_I, L_I, t).$$

It follows that at a given time the production possibility curves relating C and ΔJ for different totals of J and L are parallel straight lines with a slope equal in absolute value to $R(t)$. $R(t)$ is the ratio of the marginal costs, and in competitive conditions the ratio of the prices, of the two goods. The ratio of capital to labor employed will always be the same in one sector as in the other.

If the relative prices of C and J remain constant over time, we can use either as *numéraire* in comparing values of Y at different periods. But if they do not, we follow the spirit of many theoretical discussions in taking consumption goods as *numéraire*. Thus:

$$(6) \quad Y = C + p_t \Delta J$$

where p_t is the price of investment goods in terms of consumption goods at time t .² It follows from equation (5) that if we set $p_0 = R(0) = 1$, then:

$$(7) \quad p_t \cdot R(t) = 1,$$

since the price of investment goods in terms of consumption goods is inversely proportional to the productivities of given resources in the two sectors.

In considering the capital variable J , we disregard the fact that in any period many different kinds of capital goods are produced.³ We assume that the single type of capital good produced in a given period can be measured in units each of which is a perfect substitute in production for another unit of the same "vintage." We recognize the existence of distinct capital goods of different vintages, and assume [11] that in

¹ The problem is similar to that of community indifference curves [4]. The result in the text is proved in [5, pp. 47–51].

² Equation (6) requires deflation of money income by a price index of consumption goods rather than, as in conventional measures, by a price index of goods in general. The difference between the two measures can be shown to depend on the fraction of income invested (s) and the annual percentage increase in p_t (μ). If s were 20 per cent and μ were 1 per cent [3], and in year 0 both measures gave the same value for real income, then in year 1 real income according to equation (6) would be approximately $1 + s\mu$ ($= 1.002$) times real income as conventionally measured.

³ This problem is considered in [5, pp. 81 ff.].

each period the labor force⁴ is distributed among capital goods of different vintages in such a way as to maximize total output, Y . Hence the quantities of capital goods of different vintages E_1, \dots, E_n are represented by the single variable J in the aggregate production function (1), which is homogeneous of degree one in J and L . If we also assume that the output obtainable from each vintage of capital goods is homogeneous of degree one in E_r and L_r (the amount of labor employed with E_r), it can be shown that the relationship between J and E_1, \dots, E_n must have the following simple form:⁵

$$(8) \quad J = \sum_r \beta_r E_r.$$

This result implies that in any given period the marginal rate of substitution between capital goods of any two vintages must be a constant, independent of the amount of labor employed and of the quantities of capital goods of these or any other vintages. If we are not to have to recalculate these marginal rates of substitution continually as time

⁴ The labor force may be assumed for the moment to consist of homogeneous units; but see the second paragraph of Section II.

⁵ The proof is as follows. We have assumed:

$$Y = \sum_r F_r(E_r, L_r, t) = F[J(E_1, \dots, E_n), L, t].$$

To determine the implications of the aggregation involved, consider the total differentials [5, pp. 12-13]:

$$dY = \sum_r \left(\frac{\partial F_r}{\partial E_r} dE_r + \frac{\partial F_r}{\partial L_r} dL_r \right) = \frac{\partial F}{\partial J} \sum_r \frac{\partial J}{\partial E_r} dE_r + \frac{\partial F}{\partial L} \sum_r dL_r.$$

Since the E_r 's are free to take any values, we have for each r :

$$\frac{\partial F_r}{\partial E_r} = \frac{\partial F}{\partial J} \frac{\partial J}{\partial E_r} \quad \text{or} \quad \frac{\partial J}{\partial E_r} = \frac{\partial F_r}{\partial E_r} \div \frac{\partial F}{\partial J}.$$

Now $\partial F / \partial J$ is uniquely determined by J and L , as is $\partial F / \partial L$. With efficient allocation of labor, $\partial F / \partial L = \partial F_r / \partial L_r$ for each r . With constant returns to scale (and smoothly convex-to-the-origin isoquants), $\partial F_r / \partial L_r$ determines E_r / L_r and therefore $\partial F_r / \partial E_r$. Thus $\partial J / \partial E_r$, being the ratio of two expressions each of which is uniquely determined by J and L , is itself uniquely determined by J and L .

But E_r can change arbitrarily (provided that some other E_s also changes) without affecting the value of J or, therefore, the value of $\partial J / \partial E_r$. It follows that for each r , $\partial J / \partial E_r$ is a constant, so that we may write:

$$J = k + \sum_r \beta_r E_r.$$

A proportional change in each E_r and L_r will change Y and L in the same proportion. If Y is homogeneous of degree one in J and L , this must also increase J in the same proportion (unless $\partial F / \partial J = 0$). Hence J must be homogeneous of degree one in the E_r 's, so that k in the last equation is zero, and:

$$J = \sum_r \beta_r E_r \quad Q.E.D.$$

passes (which no one has shown any inclination to suggest), we must assume that changes in technology do not affect the relative values of the β_r 's, and that in any given period physical depreciation affects in the same proportion the values of capital goods of all vintages.

If technical change increases the output obtainable from a given amount of labor and a given collection of capital goods, we may choose to represent it in one of two ways. We either may say that the same capital and labor represent more "efficiency units" than before, and that the production function has not changed or, alternatively, we may continue to represent the same capital goods and labor by the same number of efficiency units as before (after allowing for physical depreciation of capital), and say that the production function has shifted. We shall adopt the latter course, since it facilitates the distinction among different sources of increase in productivity [2] [7].

Hence we take as our "standard unit" of capital a unit of a particular vintage (e.g., one produced in year 0) in a particular condition (e.g. brand-new). Let a brand-new capital good of vintage r be a perfect substitute for γ_r standard units; then it represents γ_r efficiency units. Of course, $\gamma_0 = 1$. If at the beginning of period t we have E_0, E_1, \dots, E_{t-1} capital goods of vintages 0, 1, \dots , $t-1$, and capital goods suffer physical depreciation at a rate δ per period (beginning in the period following that in which they are built), then:

$$(9) \quad J = \sum_{r=0}^{t-1} \beta_r E_r = \sum_{r=0}^{t-1} \gamma_r e^{-\delta(t-1-r)} E_r.$$

We take as our standard unit of labor a particular man-hour performed in year 0, and assume that the marginal rate of substitution between any other man-hour and the standard unit is a constant, independent of the quantity of capital employed and of the state of technology. A man-hour which is a perfect substitute for x standard units represents x efficiency units of labor.

In common with many writers, we assume that technical progress is Hicks-neutral in each sector, and increases the output obtainable from given numbers of efficiency units of capital and labor. The rates of technical progress are assumed for ease of exposition to be constant in each sector, but not necessarily equal. Thus:

$$(10) \quad C = e^{a_I f}(J_C, L_C); \Delta J = e^{b_I f}(J_I, L_I).$$

The output of the consumption sector is measured in units which are assumed to be comparable over time. The output of the investment sector is measured in *efficiency units* of capital as defined above.

It follows from our earlier argument that the only thing that can change the relative prices of consumption goods and efficiency units of

capital is a difference between the rates of technical progress in the two sectors. From equations (5), (7), and (10):

$$(11) \quad R(t) = \frac{1}{p_t} = e^{(b-a)t}$$

and from equations (6), (10), and (11):

$$\begin{aligned} Y &= C + p_t \Delta J = e^{at} f(J_C, L_C) + \frac{e^{bt}}{e^{(b-a)t}} f(J_I, L_I) \\ &= e^{at} [L_C \phi(J_C/L_C) + L_I \phi(J_I/L_I)] = e^{at} L \phi(J/L),^6 \end{aligned}$$

so that:

$$(12) \quad Y = e^{at} f(J, L).$$

Thus technical progress increases the output Y obtainable from given numbers of efficiency units of labor and capital at a rate equal to the rate of technical progress in the *consumption* sector. This is a consequence of our decision to measure Y in consumption units; if technical progress is faster (slower) in the investment sector, its effect on Y is reduced (increased) by a compensating fall (rise) in p_t .

II. Embodied Technical Progress

In the remainder of this paper we shall be concerned with two questions in the discussion of which the aggregate production function has been used. The first problem is to identify sources of increased productivity, the second to determine the effect on an economy's growth path of changes in the proportion of national income invested.

Of the sources of productivity increase, one will be discussed briefly, as it is not our major concern. Let productivity be defined as output per man-hour. It may be that as a result of improved education [2], experience [1], and training, a man-hour of labor comes to represent, as time passes, a greater number of efficiency units of labor as defined in the last section. Specifically, let labor measured in efficiency units (L) and in man-hours (M) be related by $L = M e^{mt}$. Then it is not difficult to show that the production function $Y = e^{at} f(J, L)$ can be written as $Y = e^{at} \psi(J, M)$ only if both $f(\)$ and $\psi(\)$ have the Cobb-Douglas form, so that:

$$(13) \quad Y = e^{at} J^\alpha L^{1-\alpha} = e^{at} J^\alpha (M e^{mt})^{1-\alpha} = e^{[a+m(1-\alpha)]t} J^\alpha M^{1-\alpha}.$$

Nelson appropriately terms this source of increased productivity "technical progress embodied in labor"; he also points out complexities sur-

⁶ As is noted in the third paragraph of Section I above, it is always true that $J_C/L_C = J_I/L_I = J/L$.

rounding the notion, among them that one should consider labor, as well as capital, as classifiable into "vintages" [7, pp. 587-88].

We take labor henceforth to be measured in efficiency units, and turn to the concept of technical progress embodied in capital. This is the part of technological advance that can be exploited only if it is incorporated in new capital goods. Embodied technical progress results in a greater output from labor employed with new capital goods only; disembodied (or more accurately unembodied)⁷ technical progress affects equally the productivity of all labor, irrespective of the vintage of the capital goods with which it is equipped. In the special case considered in the previous section, where an aggregate production function exists and efficiency units of capital can be defined, embodied progress is said to be "purely capital-augmenting" [10, p. 59]. The number of efficiency units of capital, γ_r , represented by a brand-new capital good of vintage r is greater, the larger is r —that is, the later the date at which the capital good is produced.

Now the quantities $\gamma_r E_r$ of equation (9) are measured in efficiency units. The quantities E_r themselves are not. Both Solow [11] and Phelps [8] speak of the E_r 's as being measured in "physical units," so that when embodied progress is purely capital-augmenting it takes the form of an increase over time in the number of efficiency units of capital corresponding to a newly produced physical unit. But if, as is presumably the case, later models differ in size, form, and mode of operation from earlier models, what "physical unit" has economic significance?⁸

There seem to be at least three possible answers to this question. Firstly we may assume, as Solow does in his latest contribution to the field [10, p. 29], that consumption goods and capital goods are physically identical, but that a more recently produced unit of output represents more efficiency units of capital (but no more "quality units" of consumption) than one produced earlier. This is equivalent to defining a physical unit of capital as that quantity which costs the same amount to produce as a unit of consumption goods. On this interpretation, the rate of embodied technical progress can be expressed in any one of four (approximately) equivalent ways: (i) as the rate of decline in the price of an efficiency unit of capital in terms of consumption goods; (ii) as the rate

⁷ My colleague S. G. Triantis points out that the word "disembodied" suggests that the technical progress in question was embodied at one time, and is so no longer.

⁸ The problem of defining physical units would still exist if embodied progress were not assumed to be purely capital-augmenting. In the more general case embodied progress would mean only that with equal amounts of labor, $L_r = L_{r+1}$, applied to equal numbers of "units," $E_r = E_{r+1}$, of (brand-new) capital goods of two different vintages, we should have $Y_{r+1} = F_{r+1}(E_{r+1}, L_{r+1}) > Y_r = F_r(E_r, L_r)$. But until we know the units in terms of which $E_r = E_{r+1}$, we cannot know whether embodied progress has taken place, or at what rate. One set of units might give $Y_{r+1} > Y_r$, another $Y_{r+1} < Y_r$.

of increase in the number of efficiency units of capital obtainable for the sacrifice of a unit of consumption goods; (iii) as the rate of increase in the ratio of the stock of capital measured in efficiency units to the cost, measured in consumption units, of replacing it with current models of capital goods representing the same number of efficiency units; (iv) as the difference between the rates of technical progress in the investment sector, b , and the consumption sector, a , as these rates were defined in the preceding section.

It may be argued that the foregoing is unacceptable as a general definition of embodied progress, corresponding as it does to a special interpretation of a special model.⁹ It remains true that the four expressions above are equivalent to the rate of embodied progress in at least the theoretical part of Solow's work [10]. Moreover, this is the interpretation that must be used in the analysis of the relationship between investment and growth and in the definition of Solow's one-period "rate of return," as will be shown in the next section.

A second interpretation of the rate of embodied progress is purely statistical. In the empirical part of [10], Solow builds up a number of series of the stock of capital in efficiency units by applying different "improvement factors" to a deflated investment series. The deflator is a price index of capital goods, so that the rate of embodied progress, or the improvement factor, is simply a correction of the capital-goods price index for unmeasured quality changes, and capital measured in physical units is a total of deflated, uncorrected investment figures. If our first interpretation of embodied progress had been applied, the deflator would have been a price index of consumption goods. It will be shown in the next section that, since the price indices of capital goods and consumption goods diverged, some adjustment is necessary in Solow's calculations of the "rate of return."

A third interpretation would distinguish between improvements in methods of production and improvements in models.¹⁰ Let us suppose that in year 0 given numbers of efficiency units of capital and labor can produce 100 standard units of capital. In year 1 the same efficiency units of labor and capital can produce either 102 standard units or 51 units of a new model; each unit of the new model represents 2.06 efficiency units. Then the productivity of a given number of efficiency

⁹ I defined embodied progress in this way in [5, p. 94], and in an earlier draft of this paper. Professor Solow has insisted in correspondence that this is not what he and others have meant by embodied progress in general, and J. K. Whittaker of the University of Bristol has pointed out to me that if production-possibility curves are not straight lines (as they are assumed to be in this paper), the relative prices of capital goods and consumption goods can change for reasons quite unconnected with technology.

¹⁰ If we take into account the improvements in the quality of the labor force discussed at the beginning of this section, we may distinguish improvements in *methods*, improvements in *models*, and improvements in *men*.

units of capital and labor in the investment sector has increased from 100 to $51 \times 2.06 \approx 105$ efficiency units, so that $b = 5$ per cent. This can be broken down into an improvement in methods, which would have increased output by $b' = 2$ per cent (from 100 to 102 efficiency units) if there had been no model improvement, and a further $b'' = 3$ per cent because of the new model. The rate of model improvement in the investment sector seems to me to correspond, within this framework, to a common-sense notion of technical progress "embodied" in new capital goods.

But once we have distinguished improvements in models and methods in the investment sector, is there not an analogous distinction in the consumption sector? May we not also split a into a' (unembodied improvements in methods of production) and a'' (improvements in quality)? If this is done, the relationship between our first interpretation of capital-embodied technical progress as $(b-a)$ and our third as b'' becomes interesting. They clearly come to the same thing only if $b'' = b-a$, so that $a = b'$. A special case is Solow's model in [10], where *all* technical progress is embodied in new capital goods, so that $b'' > 0$ and $a = a' = a'' = b' = 0$. But what of the "purely disembodied" case of Solow's celebrated 1957 article [12]? If our two interpretations are to be reconciled, we must have $a = b$ and $b'' = 0$. This requires that the rate of unembodied progress in the investment sector (b') equal the over-all rate of progress in the consumption sector (a).

These, however, are special cases. There is no reason why a' , a'' , b' , and b'' should obey such restrictions. And I do not see that there is any great advantage, either theoretical or empirical, in distinguishing between improvements in methods and improvements in models. But there is no doubt that very great economic significance attaches to $(b-a)$, the difference between the over-all rates of technical progress in the two sectors. This, I contend, is what Solow and Phelps mean implicitly by the rate of embodied technical progress, though it corresponds to the common-sense meaning of the term only in special cases. Moreover, since there is no reason why the rate of technical progress in the consumption sector should not exceed that in the investment sector, embodied technical *regress* ($b-a < 0$) is perfectly possible, on this definition.

But whether we call it the rate of embodied technical progress, or the excess of the rate of technical progress in the investment sector over that in the consumption sector, is it true that $(b-a) > 0$? If we had price indices of capital goods and consumption goods which made proper allowance for quality changes, the question could be easily settled. Moreover, deflation of investment by the capital-goods price index would yield an estimate of the stock of capital in efficiency units, and

the value of a could then be estimated by the method of Solow's 1957 article [12].

Published price indices for the United States [3] show the prices of capital goods rising faster than those of consumption goods at the rate of about 1 per cent per annum. If these indices were acceptable, they would of course imply that $a > b$. It is widely believed that the capital-goods price indices underestimate quality improvements. But presumably price indices of consumption goods err in the same direction—and this error, while it would not in itself affect estimates of the stock of capital measured in efficiency units, would certainly lead to underestimates of the rate of growth of real income and of the value of a . Until it is possible to determine the sign of $(b-a)$, we do not know whether to second Solow's endorsement of the view [11, p. 62] that our children's saving will be more fruitful than our own.

III. *Savings, Growth, and the Rate of Return*

The aggregate production function and the concept of embodied technical progress have been used in discussions of the effect of a change in the investment ratio on the rate of growth, and of the rate of return on investment. It will be shown in this section that the two sectoral rates of technical progress a and b are crucial in these discussions, and that, in so far as the rate of embodied progress is relevant, it is only when it is interpreted as $(b-a)$.

Let us specialize the production function (12) to the Cobb-Douglas form:¹¹

$$(14) \quad Y = e^{at} J^{\alpha} L^{1-\alpha}.$$

J is measured in efficiency units. Let us write K for capital measured by its replacement cost in terms of consumption goods, i.e., the cost of replacing it by J efficiency units of capital of the latest model, produced by the latest methods. Then, as was seen in the last section:

$$(15) \quad J = e^{(b-a)t} K.$$

Let us assume that L grows at the constant rate n , so that $L(t) = L_0 e^{nt}$. Then, writing G for rates of growth:

$$(16) \quad G_Y = a + (1 - \alpha)n + \alpha G_J = a + (1 - \alpha)n + \alpha(b - a) + \alpha G_K.$$

Of the many assumptions we could make about savings, we shall select two. One is Phelps's [8, p. 553], that gross savings and gross investment are a constant fraction of gross income, Y . To obtain net invest-

¹¹ Matthews [6] has argued that some of the substantive results of this section will not hold if the production function has some other form, but this does not affect the point we seek to make.

ment from gross investment, or net income from gross income, when all are measured in terms of consumption goods as *numéraire*, we deduct physical depreciation at the rate δ , and subtract capital losses at the rate $(b-a)$ if $b > a$, or add capital gains at the rate $(a-b)$ if $a > b$, because of the changing price of an efficiency unit of capital in terms of consumption goods. Thus:

$$(17a) \quad \frac{dK}{dt} = sY - (\delta + b - a)K.$$

Alternatively we may assume that net investment is a constant fraction of net income, so that:

$$(17b) \quad \frac{dK}{dt} = s[Y - (\delta + b - a)K].$$

Since $G_K = 1/K(dK/dt)$, we obtain from (16), (17a), and (17b) two expressions for G_Y :

$$(18a) \quad G_Y = a + (1 - \alpha)n + \alpha \left(s \frac{Y}{K} - \delta \right)$$

$$(18b) \quad G_Y = a + (1 - \alpha)n + \alpha \left[s \frac{Y}{K} - s\delta + (1 - s)(b - a) \right].$$

In either case, if a , b , δ , s , α , and n are all constant, a constant rate of growth requires that Y/K be constant, so that $G_Y = G_K$. Then (16) gives:

$$(19) \quad \bar{G}_Y = \frac{a + \alpha(b - a) + (1 - \alpha)n}{1 - \alpha} = \frac{(1 - \alpha)a + \alpha b + (1 - \alpha)n}{1 - \alpha}.$$

This rate of growth, as is well known, is independent of s .

The "total" rate of technical progress (equal to the constant rate of growth of output per efficiency unit of labor) may be expressed as $1/(1-\alpha)$ times: *either* (i) $a + \alpha(b-a)$, the rate of unembodied technical progress plus α times the rate of embodied technical progress;¹² *or* (ii) $(1-\alpha)a + \alpha b$, the weighted mean of the rates of technical progress in the consumption sector and the investment sector, the weights being the elasticities of output with respect to labor and capital respectively.

We follow Phelps [8, pp. 561 ff.] in working out the speed of adjustment to a given equilibrium rate of growth after, say, a change in the savings ratio. The first equation of each pair is Phelps's result based on the gross savings assumption (17a); the second is based on the net savings assumption (17b). Multiplying (18a) and (18b) by Y , we obtain

¹² What is here called $(b-a)$ corresponds to λ in Solow [10], but to λ/α in Phelps [8].

the differential equations:

$$(20a) \quad \frac{dY}{dt} = [a - \alpha\delta + (1 - \alpha)n]Y + \frac{\alpha s Y^2}{K}$$

$$(20b) \quad \frac{dY}{dt} = [a - \alpha\delta s + (1 - \alpha)n + \alpha(1 - s)(b - a)]Y + \frac{\alpha s Y^2}{K}.$$

Replacing K by J by means of (15), and solving for J in terms of Y by means of (14), we have:

$$(21) \quad \frac{Y^2}{K} = Y^{2-(1/\alpha)} e^{[a+\alpha(b-a)+(1-\alpha)n]t}.$$

The speeds of adjustment which emerge from the solutions to these equations are (*cf.* [8, p. 561]):

$$(22a) \quad \rho' = b + (\delta + n)(1 - \alpha)$$

$$(22b) \quad \rho'' = b + (\delta + n)(1 - \alpha) - (1 - \alpha)(1 - s)(\delta + b - a).$$

By means of (19) we may conveniently express these results in terms of the equilibrium rate of growth \bar{G}_Y , as follows:

$$(23a) \quad \rho' = (1 - \alpha)[\bar{G}_Y + \delta + b - a]$$

$$(23b) \quad \rho'' = (1 - \alpha)[\bar{G}_Y + s(\delta + b - a)].$$

Consider two economies with the same long-run equilibrium rate of growth \bar{G}_Y and the same values of α and δ , but with different values of a and b . Under the gross savings assumption, (23a) shows that if s is increased the speed of adjustment to the new and higher growth path will be more rapid in the economy with the higher rate of capital-embodied progress in our first sense—that is, in the economy in which the rate of technical progress in the investment sector exceeds that in the consumption sector by more (or falls short of it by less). On the net savings assumption, (23b) also shows that the speed of adjustment will be greater, the greater is $(b - a)$. If $(\delta + b - a)$ is positive, however, the speed of adjustment will be less than on the gross savings assumption, and more rapid, the larger is the new value of s .

We conclude with a comment on the “rate of return.” “The thought-experiment is to sacrifice one unit of consumption at time t in favor of investment, and then ask what is the largest increment of consumption that can be enjoyed at time $t+1$ without impairing consumption possibilities in any future period” [10, p. 60]. Solow’s expression is [10, p. 61]:

$$(24) \quad r = \left(\frac{\partial Y}{\partial J} \right)_t - \frac{\delta + \lambda}{1 + \lambda}$$

where $(\partial Y/\partial J)_o$ is the gross marginal product of J , δ is the rate of physical depreciation, and λ is the rate of embodied technical progress. This can be shown to be equivalent to the rate of profit in terms of consumption goods as *numéraire* (cf. [9, p. 40]):

$$(25) \quad r = \frac{1}{p_t} \left(\frac{\partial Y}{\partial J} \right)_n + \frac{1}{p_t} \frac{dp_t}{dt}$$

where p_t is the price of an efficiency unit of capital, $(\partial Y/\partial J)_n$ is the net marginal product of J , and λ is interpreted as the rate of increase per period in the number of efficiency units of capital obtained for a unit of consumption goods sacrificed.¹³

The rate of embodied progress relevant for these calculations is of course the $(b-a)$ of our first interpretation. But the λ calculated by Solow in the empirical part of [10] is the correction of the capital-goods price index of our second interpretation. The calculation which would have yielded an estimate of $(b-a)$ (or rather, since Solow assumes $a=0$, of b) would have resulted, as was noted earlier, from a deflation of investment by a price index of consumption goods. Since the price index of consumption goods rose less rapidly than that of capital goods, deflation by the former would have given a more rapidly rising series of uncorrected investment figures, and a smaller "improvement factor" would have had to be applied to yield a given stock of capital in efficiency units. The difference in the rates of growth of the two price indices was roughly 1 per cent per annum, so that Solow's favored estimate of .05 for λ corresponds to a value of about .04 for $(b-a)$. Of the components of the rate of return [10, p. 89], the only one significantly affected is the deduction for "obsolescence,"¹⁴ $\lambda/(1+\lambda)$, which becomes roughly .04 rather than .05, yielding a rate of return of .27 rather than .26. This is, of course, not the only adjustment which should ideally be made in Solow's calculations—others follow from the desirability of allowing a as well as b to be positive, from the possibility of improvements in men, as well as in methods and models (see the second para-

¹³ Solow implicitly assumes that $p_t=1$, so that

$$p_{t+1} = \frac{1}{1+\lambda}; \quad \frac{1}{p_t} \frac{dp_t}{dt} = -\frac{\lambda}{1+\lambda}.$$

Since depreciation of capital goods constructed in period t does not begin until period $t+1$,

$$\frac{1}{p_t} \left(\frac{\partial Y}{\partial J} \right)_n = \frac{1}{p_t} \left[\left(\frac{\partial Y}{\partial J} \right)_o - \delta p_{t+1} \right] = \left(\frac{\partial Y}{\partial J} \right)_o - \frac{\delta}{1+\lambda}.$$

Thus the equivalence of the two expressions for r , (24) and (25), is established.

¹⁴ See also [8, pp. 565-66]. According to normal usage, the "rate of obsolescence" would correspond to the rate of model improvement, b' , in our third interpretation of embodied progress. This, as was pointed out earlier, is equal to $(b-a)$ only on special assumptions.

graph of Section II above), and from the discrepancy between conventional and theoretical measures of income (see footnote 2). The present minor modification is stressed only to illustrate the difference between the first and second of our interpretations of embodied technical progress.

IV. Summary

The usual aggregate production function model can be shown to commit its users to the assumption that the relative prices of capital goods and consumption goods are independent of their outputs, and change over time only as a result of a difference between the rates of technical progress in the investment sector and the consumption sector. For the purpose of this argument the output of the investment sector is measured in "efficiency units" of capital, where an efficiency unit of capital or labor is that amount which is a perfect substitute for a standard unit produced or performed in a given base period. Technical progress is assumed to take the form of a Hicks-neutral increase in the output of given numbers of efficiency units of capital and labor so defined.

The rate of "embodied technical progress" used by Solow and Phelps in discussions of the effect on short-run and long-run growth of an increase in the fraction of income invested, and in calculations of the "rate of return," must be interpreted as the excess of the rate of technical progress in the investment sector over that in the consumption sector. There is no reason in principle why this should be positive. Only on special assumptions does this interpretation correspond to the common-sense notion of capital-embodied technical progress as the development of new *models* of capital goods, as contrasted with unembodied progress as the development of new *methods* of producing goods of a given type.

COMMUNICATIONS

Steel Imports and Vertical Oligopoly Power: Comment

In the *American Economic Review* of September 1964 [1, pp. 626-55], Walter Adams and Joel Dirlam criticize the domestic steel industry on a number of counts—particularly regarding technology, production, pricing practices, vertical integration, and imports. This communication will be limited to an examination of the authors' contentions about steel industry technology. Although several other assertions of the authors justify a re-examination, space limitations are such that this communication will not be able to examine these in the detail necessary.

The authors contend that U.S. steel producers have lagged behind foreign producers in investing in technologically improved facilities and, further, that they have invested in obsolete equipment and that improvements have been adopted only when the industry has been forced to do so by the increasing pressure of foreign competition [1, pp. 626, 646]. To support their charges, the authors cite the examples of the oxygen furnace and the continuous-casting process.

Specifically, the authors state that during the 1950's, the U.S. steel industry bought 40 million tons of the wrong kind of capacity, namely the open-hearth furnace. They state that "Much of the U.S. industry's current investment in plant and equipment is calculated not to add to capacity, but to correct the embarrassing investment errors of the last decade" [1, p. 627].

Increases in open-hearth capacity in the steel industry are shown in Table 1.¹

Although there was a net increase in open-hearth capacity of nearly 40 million tons, only about 16¼ million tons were accounted for by the construction of *new* facilities during this period. Further, the steel companies built only 5.6 million tons of *new* open hearths—not 40 million tons—during the portion of this period following 1953, when information about the oxygen furnace first became generally available to the industry. The remainder of the increase in capacity represented the results of improved utilization of *existing* facilities—an approach which the steel companies found to be economically more desirable than construction of completely new facilities.

The authors surely do not mean to imply that a fully integrated steel mill has complete control over the fluidity of its capital use. On the contrary, most of the capital becomes sunken and fixed once it is brought into being. The best that can be done in connection with technological changes is to attempt to keep the existing physical plant from becoming uneconomical to operate by making steady improvements and modernizations as these become technologically and financially feasible. It is only in the construction of new facilities

¹ Based on American Iron and Steel Institute data.

TABLE 1—INCREASE IN OPEN-HEARTH STEELMAKING CAPACITY BETWEEN 1950 AND 1960

	Increases	Decreases	Net Tonnage Change in U.S.
Revision of ratings of existing furnaces*	31,569,060	2,561,600	29,007,460
New furnaces	16,250,760	—	16,250,760
	47,819,820	2,561,000	45,258,220
Less: Old furnaces abandoned	—	5,621,080	5,621,080
Net Increase			39,637,140

* Primarily due to the use of oxygen in existing furnaces, introduction of labor-saving equipment, and better refractories.

that a firm has the option of using existing technology or new methods, even if the latter were operationally suitable at the time.²

The authors assert that while the U.S. steel industry was emphasizing open hearths, the European and Japanese firms were instead installing oxygen furnaces at a "breakneck pace" [1, p. 627]. The record shows, however, that from 1953 to 1960 the U.S. producers increased their open-hearth capacity by only about 23 per cent in contrast with an increase of about 79 per cent for members of the European Coal and Steel Community and of approximately 169 per cent for Japan.

The authors criticize the U.S. industry for being slow to adopt the oxygen process in spite of its alleged *widespread* use in Europe more than ten years ago [1, p. 647]. The oxygen process was first used commercially in Austria in 1952 on two 35-ton furnaces with an annual capacity of about 400,000 tons. In Europe, another shop was started in 1953, still another in 1955, one more in 1956, two more in 1957, four more in 1958, and two more in 1959. The total capacity of all these operations approximated 4,000,000 net tons. An additional five shops were started up in 1960, bringing the total oxygen-furnace capacity in Europe by 1960 to about 5.3 million net tons. These data obviously cannot be interpreted to mean that oxygen-furnace-produced steel was *widespread* in Europe ten years ago. In fact, as late as 1963, only about 6 per cent of the steel produced in Europe was made by oxygen furnaces; this compares with about 7½ per cent in the United States by 1963. By this measurement, U.S. producers were technologically ahead of—not behind—European producers.

To understand the rate of introduction of the oxygen furnace in the United States, it is necessary to examine both economic and engineering factors. The

² Subsequent discussion will indicate why such a choice was not present for much of the period.

early oxygen furnaces used in Europe had insufficient capacity to meet the requirements of the large, integrated steel mills of the United States, where many of the open hearths were producing heats (i.e., "batches") of 300 to 500 tons.

Although it would have been possible for large, integrated U.S. mills to have constructed a number of small oxygen furnaces, there are two apparent reasons why it was not economically desirable for U.S. producers to do this. First, large producers undoubtedly determined that their large open-hearth furnaces were more efficient in producing large tonnages than a large number of small-capacity oxygen furnaces would be. This, of course, would not have precluded the very small U.S. producers from constructing small oxygen furnaces, since these producers did not have the same need for volume; generally, however, these *very small steel producers do not have blast furnaces*, which are a prerequisite to an oxygen steelmaking operation. A second reason why U.S. producers deferred making investments in oxygen furnaces is undoubtedly that they felt they could develop higher-capacity oxygen furnaces in the not-too-distant future and that such furnaces would be much more efficient than small-capacity furnaces, which were the only type that could have been built during this earlier time period. To make the oxygen furnace feasible for widespread use in the United States, a great deal of research and development first had to be undertaken; this was to come at a future date.

At present, some 300-ton oxygen furnaces are already in operation in the United States and others are being built, but the average-size oxygen furnace now in operation in the United States is about 140 tons. Until the large oxygen furnaces were developed, a number of companies adapted their large, modern open-hearth furnaces with oxygen lances and have operated them as efficient production units. In light of these facts, it seems quite apparent that there would have been little or no advantage to the major U.S. companies from oxygen furnaces, rather than continued use and improvement of the existing open hearths, during the years before the large oxygen furnaces were perfected.

The process of the introduction of the oxygen furnace is neither hit-or-miss nor one of massive replacement. Companies tend to replace the oldest and highest-cost open hearths first, and only replace those where capital could not be utilized more efficiently elsewhere. Now that 150- and 200-ton furnaces have been engineered, one company after another is building this type of capacity.

So long as steel produced by conventional methods can compete with that produced by newer technology, it would not be a wise economic decision to scrap the existing facilities and to destroy vast investments in fixed capital. It can be expected that newer technology will become more general as old facilities wear out and are scrapped. This is why it is unlikely that there will be any future purchase of *new* open-hearth capacity, but there will continue to be modifications, adaptations, and modernizations of such facilities so long as they are cost-competitive. Any decision that involves the contemplated scrapping of open hearths and their replacement by oxygen furnaces is carefully weighed against the alternative uses of funds.

Another aspect of technology that the authors discuss involves the use of continuous casting, a process made economically practical as a result of the oxygen furnace. Continuous casting at the present time involves an uninterrupted process of steelmaking and steel-forming of in-process shapes for future conversion. The authors again claim that the U.S. industry adopted the continuous-casting method slowly and only with great reluctance. But, once again, it is necessary to point out that the structure of steelmaking operations in the United States is very different from that in Europe, and that the size of the economical producing unit in the United States is much larger. Even in the United States, the mills that found it economical to adopt continuous-casting techniques at first were the smaller plants.

Although the authors do indicate that continuous casting abroad "began to move into high gear about eight years ago," they do not add that most of the 40 machines installed from 1955 to 1962 had very small capacities. Only 10 of the 40 had annual capacities in excess of 100,000 tons, and the largest was rated at about only 350,000 tons. This contrasts with modern blooming and slabbing mills (which they replace) in the United States that have annual capacities in excess of 3,000,000 tons.

Although it would have been possible for large, integrated U.S. producers to construct small continuous-casting units at an earlier date, such an approach would undoubtedly have resulted in higher unit costs. For the small producer, however, who could not produce the volume of steel necessary to make the operation of large-volume blooming, slabbing, and billet mills feasible, small-capacity continuous-casting units were economical. Continuous casting was not installed by any large producers until a large-scale process was developed which would be more efficient than what the producer had at the moment, and until the return on such an investment was anticipated to be higher than any alternative use of funds.

In summary, with reference to technological advances, it is imperative to recognize that the introduction of new methods is not dictated solely by the availability of a new process. The very technological nature of the industry itself affects the wide use of newer methods, since early applications may be restricted to smaller producing units. It also is important to recognize that a basic factor affecting decisions about investments is consideration of alternative uses of money. There are many ways that a firm can spend funds for investment in plant and equipment. The key decision is to spend the monies where they will earn the best returns. With different rates of growth in demand in the United States, Europe, and Japan, the facility decisions necessarily must be different. With rapidly expanding demand, it is financially possible for a firm to install new capacity; without such growing demand, alteration of existing facilities frequently is a more economical move.

Steel Imports and Vertical Oligopoly Power: Comment

Walter Adams and Joel Dirlam in their recent article set out to examine "the comparative showing of the U.S. steel industry in an increasingly competitive world economy" [1, p. 626]. They feel that the increase in steel imports from 1.2 per cent to 5.6 per cent of total domestic consumption from 1955 to 1962 is symptomatic of a failure on the part of the steel industry. Five substantial causes are then produced to explain the supposedly poor comparative showing.

Three of the causes, "the recovery from wartime destruction and the dismantling of the European and Japanese steel industries," "a substantial increase of world-wide capacity," and "a generally export-orientated price policy by European and Japanese producers" [1, p. 626], were of course beyond the direct control of the U.S. steel industry. But, these three causes along with the relatively low U.S. steel tariffs would yield a significant tendency in themselves for steel imports to increase. A judgment of the U.S. steel industry such as the authors attempt should then start with an assessment of the impact of these exogenous causes. Therefore we are surprised that the authors do not attempt to weigh the effects of the better age structure of foreign capital.¹ Nor do they assess the impact that changes in world overcapacity had on the strength of export market competition during the period considered.² Further they cast doubt on the prevalence of "dumping" in stating that the Japanese "could not be convicted of dumping—even in an arithmetic sense—because their U.S. prices were identical to their home market prices" [1, p. 649]. Yet, what was absorption by Japanese exporters of the transport costs between Yokohama and Pittsburgh must be termed either charity or dumping.

Although an evaluation of the impact of these causes, along with low steel tariffs, is absolutely basic to a sensible discussion of other factors which might contribute to increased steel imports, almost the whole article is devoted to an analysis of "vertical oligopoly power." The authors accordingly assign as a fourth cause of higher steel imports "a generally insensitive, utility-like, administered price policy by domestic producers" [1, p. 626].³ The authors at-

¹ The question of whether older capital in general puts a competitor at a disadvantage is a controversial problem which has received much attention [3] [4]. The great importance of an integrated plant in efficient steel production, it could be argued, is a classic case of Marvin Frankel's "interrelatedness" putting the older industry at a disadvantage [3]. The authors' presentation leaves one unsure as to the importance which they attach to the older age structure of the U.S. industry as a cause, in itself, of increased steel imports. An estimation of the decisiveness of this cause would seem to be logically prior to the rest of their arguments.

² There was a chronic shortage of steel capacity outside the United States which ended only in the middle and late 'fifties.

³ The authors state: "this is not to gainsay the fact that transaction prices occasionally deviate from quoted prices, that there is some off-list selling, and that there are some temporary (though short-lived) dips in the steel index. The trend of the steel price structure, however, is unmistakably and unidirectionally upward" [1, p. 628, n.]. Facing increased competition, one would expect U.S. steel firms to become more willing to employ off-list selling, quantity discounts, and other competitive devices not included in

tempt to prove that it was the vertically integrated structure of the steel industry which produced what they feel was lack of price response to foreign competition. The authors base their proof on the experience in the wire-rod market. They present three explanatory hypotheses of "the lack of price response" to wire-rod imports in ascending order of likelihood:

1. . . . the vertically integrated firms were simply inept.
2. . . . the squeeze—particularly the delicate but excruciating additional twist of the maintenance of rod prices between 1959 and 1962—was deliberate, and designed to rid the fabricating end of the industry of price competition by independents.
3. Given the tapered integration and dual distribution in the wire segment of the industry, the majors had to compete with their nonintegrated customers [in finished steel products made from wire rod]. As long as the independent fabricators continued to buy domestic rod—and most of them used a 50/50 mix of imported and domestic rods in order not to cut themselves off from domestic supply sources—the majors felt that price cutting in the products market would not get out of hand. On the other hand, if the majors had matched the lower prices of imported rods, this would have lowered costs for the nonintegrated fabricators and served as a *carte blanche* invitation to cut product prices further than they had already been cut [1, pp. 645-46].

These hypotheses are not altogether implausible explanations of the lack of a price response in wire rod, yet even in this limited context doubts arise. For instance, why did independent fabricators continue to buy 50 per cent of their wire-rod imports at a supposedly higher price from domestic producers "in order not to cut themselves off from domestic supply sources" [1, p. 645] when overcapacity in the world wire-rod sector is evidently a problem which will continue far into the future?

The problem with these hypotheses relating vertical integration to increased steel imports is that they are logically inapplicable to imported steel products in general. Wire rod is a wholly atypical product of which only 20 per cent of the output is sold by majors, the rest being retained for in-plant fabrication into finished steel products [1, p. 640]. Perhaps because of its vertically integrated market, its price rose substantially more quickly in the period considered than finished and semifinished steel products in general [1, p. 634]. These hypotheses are relevant only to product markets where the majors are suppliers to and competitors of independent fabricators, i.e., wire rod. In such a vertically integrated market, the majors must consider the impact of a price reduction of a product upon the markets for goods fabricated from that product by both the majors themselves and their competitor-customers. Among the great bulk of steel products which are imported, the majors did not have to worry about price competition in other markets from their customers because

the index over the period. If the increased use of these techniques was substantial, the effective price of most steel products, including wire rod, may well have declined slightly after 1959.

the majors did not retain any significant quantity for further fabrication. Therefore, the vertical integration explanation simply lacks generality.

The authors envisage the steel industry as one where "if vertical integration were irrelevant to price behavior," the major firms would respond to the influx of low price imports by "meeting it frontally, in the form of price reductions" [1, p. 653]. Yet there are many reasons why the U.S. industry might not have met competition with price reductions aside from vertical integration. One motivation may have been a belief that it was not worth risking a full-scale price war in order to save a small part of the market. For instance, the industry was confronted with competition from Japan where there was "government pressure upon the industry to export at least enough to cover the cost of their substantial raw material imports . . ." [11, pp. 344-45]. In such a situation, it is likely that a price reduction by the domestic industry would bring a further price reduction by foreign competitors and eventually lead to a rapid downward price spiral.⁴

Another possible reason for not wishing to cut prices was the diversified nature of the U.S. steel industry. Most large U.S. producers make many finished products from steel ingots. One feature of the U.S. industry is that most firms have much more finishing capacity than ingot capacity. As the steel industry was faced with foreign competition in only some of its finished products, it may have been more rational for it to continue to sell as much of the product facing foreign competition as possible near the usual price and concentrate on the more profitable items. These and many other possible reasons for the lack of price response are not discussed by the authors.

The authors' fifth cause is "the installation of ultramodern capacity, reflecting the latest technology outside the United States" [1, p. 626]. By "ultramodern" the authors mean the utilization of such new processes as the oxygen converter and continuous casting. Adams and Dirlam attempt to attribute supposedly disadvantageous changes in relative production costs to the allegedly slower adoption of these technical innovations in the United States. Let us see what impact the relative speed of adoption of these new techniques had on domestic and foreign prices. The authors quote *Business Week* as an authoritative source: "During the 1950's . . . 'the industry bought 40 million tons of the wrong kind of capacity—the open hearth furnace,' while the Europeans and Japanese were installing the cheaper and more productive oxygen converters at a breakneck pace" [1, p. 627]. In reality, the oxygen converter was first put into production in Austria in the early 1950's, but in a form suited for that country's particular requirements and not the requirements of the U.S. [2, p. 167]. The oxygen converter was later modified and did make headway in world steel production but hardly at a breakneck pace. In the European Iron and Steel Community, only \$210,000 was spent on oxygen converters in 1955 and this rose to \$33 million only in 1960 [6, p. 65]. Even in 1960, the European Community steel industry was spending \$50 million on that "wrong kind of capacity," the open hearth, 50 per cent more than on oxygen converters. Japan was installing the oxygen converter at only a slightly

⁴ For instance, one major Belgium firm was forced to reduce its wire-rod price from about \$112 per ton in 1960 to \$75 per ton in September, 1963 [11, p. 354].

faster pace than Europe and then mainly after 1958 [10]. The authors argue that "despite these apparent advantages of the oxygen techniques and despite its widespread use in Europe more than ten years ago, the U.S. steel industry was slow to adopt it" [1, p. 647]. Yet, even by 1960, only 2.6 per cent of the European Iron and Steel Community's installed capacity was in oxygen converters and only by 1963 had it reached 10 per cent [7, p. 36]. Yet, by then the United States capacity in oxygen converters was the same as the Community's at 10 per cent of capacity [7, p. 36] [5, p. 2]. Adams and Dirlam are misled in their view that oxygen conversion was adopted sufficiently more quickly by competing foreign steel firms so as to give them a significant price advantage.

The authors believe that the adoption of "continuous casting" represents another U.S. failure. They are credulous enough to use a continuous-casting-equipment manufacturer as a source of estimates of the "remarkable cost savings for continuous casting" [1, p. 647]. It is true that continuous casting has great cost-savings potential, but even an equipment manufacturer would not deny the great technical difficulties involved and the many major modifications since the original design [9].⁵ Putting their faith in *Iron Age*, the authors note that continuous casting "'began moving in high gear abroad about eight years ago'" [1, p. 647]. However, High Authority publications consider continuous-casting investment expenditures negligible until 1962 and then they totalled only \$2.3 million [6, p. 23]. Yet, the authors state that in the United States "the first commercial continuous-casting unit went into operation in 1962" [1, p. 647].⁶ Japanese expenditure on continuous casting was only slightly higher than the Community's while England's was even lower [8, pp. 43-44].

The reliable technical literature reveals that the United States was not significantly slower than Europe and Japan in adopting this new equipment and in no case was the percentage of capacity in these new techniques high enough in the period under consideration to have an appreciable impact on relative costs.

It may well be that the increase in steel imports to the United States was the fault of the U.S. steel industry and it is possible that vertical integration was a contributory factor. Yet Adams and Dirlam have done little to prove their point.

G. A. HONE AND D. S. SCHOENBROD*

* The authors were graduate students of Nuffield College, Oxford, when this comment was written. Mr. Schoenbrod is now a student at the Yale Law School. They wish to thank Professor Lance Davis, Professor William Gorman, Sir Roy Harrod, Paul Rock, Robert Skidelsky, and, above all, Philip Andrews for valuable help. Any mistakes this comment may contain, however, are the responsibility of the authors.

⁵ One outstanding documentation of the engineering complexities of continuous casting is K. P. Korotker, *et al.*, *The Continuous Casting of Steel in Commercial Use*, Oxford (1960).

⁶ There was at least one continuous-casting plant in operation in the U.S. in 1957.

Steel Imports and Vertical Oligopoly Power: Reply

The riposte from Pittsburgh was predictable. Not so the attack from the birthplace of full-cost pricing. Avoiding repetition, we shall deal with each separately.

I

Professor Slesinger offers four principal contentions to justify the laggard innovation rate of the U.S. steel industry with respect to the oxygen converter and continuous casting.

1. He claims that only 16.25 million tons of "new" open-hearth capacity were constructed between 1950 and 1960. This is based on unpublished (and hence not readily verifiable) data of the American Iron & Steel Institute. In response to our own inquiries, the Institute placed the *net* increase in steel capacity (of all varieties) at 49 million tons during the period,¹ while most of the major steel companies refused to disclose the extent, nature, or cost of their capacity "revisions" with any degree of particularity. A sample comparison of the 1951 and 1960 AISI Directories, however, reveals that during this period U.S. Steel added a *net* of 9 new open-hearth furnaces at Fairless, 2 at Fairfield, and 1 at Geneva; Bethlehem, 7 at Sparrows Point, 5 at Lackawana, and 1 at Steelton; Republic, 6 at Cleveland; Jones & Laughlin, 6 at Pittsburgh and 2 at Cleveland; Inland, 7 at Indiana Harbor; National, 2 at Weirton; Armco, 3 at Middletown; Youngstown, 8 at Indiana Harbor; Colorado Fuel, 1 at Pueblo; and Kaiser, 2 at Fontana. These *net* additions *alone* were accompanied by an increase of 21.96 million tons of capacity. That they occurred during a period when the total number of open-hearth furnaces for the

¹ Letter to authors, June 4, 1964. Since early 1964, the AISI Library in New York bars access to the general public, including professors of economics.

industry actually decreased (from 947 to 906), and in the face of admittedly numerous abandonments, indicates that the *gross* installation of such furnaces far exceeded the AISI estimate reported by Slesinger.²

Aside from the fact that capacity "revisions" are not costless,³ this numbers game is quite irrelevant. Whether the construction of *new* open hearths amounted to 16.25 million tons (Slesinger) rather than 40 million (*Business Week*),⁴ 49 million (*Forbes*),⁵ or 48.6 million (Department of Commerce),⁶ the central question remains, as we shall show *infra*, why the U.S. steel giants constructed a single ton of new, or "revised" a single ton of old, open-hearth capacity, rather than scrapping their entire investment in an obsolescent, non-competitive process.

2. Slesinger argues that the failure of the U.S. steel giants to install oxygen converters between 1950 and 1960 reflected a preference for "large" open hearths over "small" converters and a desire to await the upscaling of an embryonic innovation. This unsubstantiated *ex post* rationalization of steel industry behavior is contradicted by persuasive circumstantial evidence.

First, the alleged dichotomy between "large" open hearths and "small" converters is purely mythological. In 1954, the U.S. Steel Corporation had 263 basic open-hearth furnaces, and only 18 of these (6.84 per cent) had an annual capacity greater than that of the "small" (35-ton heat) Austrian converters [3]. In 1957, some 88 per cent of U.S. Steel's basic open-hearth furnaces still had a smaller annual capacity than the "small" 1953-vintage Austrian converters [4]. Also in 1957, when Jones & Laughlin began operating its 85-ton oxygen vessel (with an annual capacity of 475,000 tons), not even the largest open hearths of the largest steel companies could match its capacity. (See Tables 1 and 2.) Indeed, while Slesinger talks about "large" 300- to 500-ton open hearths, the number of such furnaces—as late as 1960—accounted for only 5 to 10 per cent of the industry's total [5].

Second, Slesinger seems to confuse the influence of *firm* size with the technological imperatives flowing from *plant* size. The optimum-sized oxygen con-

²The degree of understatement in our sample is illustrated by the case of Detroit Steel, a small producer. Between 1951 and 1960, according to the AISI Directories, the number of open hearths at the company's Portsmouth plant *decreased* from ten to five, while annual open-hearth capacity *increased* from 650,000 to 1,000,000 tons. This capacity increase was achieved by scrapping ten old 100-ton furnaces and replacing them with four 250-ton and one 275-ton furnaces during the period. Thus a 1,000,000 ton *gross* addition of *new* capacity was "concealed" by a *net* capacity increase of only 350,000 tons and an actual *decline* in the *number* of open hearths operated at the Portsmouth plant. (Cases of this sort would not, of course, show up in our sample.)

³Thus, one company modernized (i.e., "revised") its open-hearth capacity during the 1950's at a cost of \$19 per ton of added annual capacity. The same company during the early 1960's installed *new* oxygen converters at a cost of only \$13 per annual ton. Letter to authors, May 19, 1964.

verter, even in a giant firm, is related to the complementary facilities of the plant in which it is installed, and there is a wide range of size feasibility—35 to 300 tons per heat—for efficient converter operation.⁷ Thus, the nation's largest steel firm (U.S. Steel) installed a 150-ton converter in 1964, whereas the fifth-largest producer (National) had been operating a 300-ton converter since 1961. Firms of such disparate size as Inland and Wheeling both use ca. 225-ton converters, and U.S. Steel and Pittsburgh both use 150-ton vessels. Certainly, if a "large" firm like Jones & Laughlin found it profitable to use a "small" 85-ton oxygen converter in 1957, can it reasonably be argued that other steel giants—i.e., U.S. Steel and Bethlehem—had to wait an additional seven years before making a similar cost-saving move?

The "scale" argument is simply no defense for innovative lethargy. As early as 1954, 10 "small" 35-ton Austrian converters, if installed at U.S. Steel's giant Fairless Works, could have matched the capacity (2,200,000 tons) of the plant's 9 "large" 290-ton open hearths. Even if this was thought inadequate, however, the converter's adaptation to the "large-scale" needs of the

⁷ It is noteworthy that the 30-ton-per-heat Bessemer converters operated by U.S. Steel at its Lorain Works in 1960 each had an annual capacity of 300,000 net tons, i.e., a larger capacity than most of the Corporation's open hearths [5, p. 355]. In 1964, U.S. Steel still found it profitable to operate *bottom-blown* Bessemer converters no larger than 35 tons per heat [6, pp. 269-308]. How, then, can it be argued that the Corporation would have been unwise to install *top-blown* converters of the same "small size ten years earlier,

U.S. industry would hardly have taken 10 years—had the steel executives invested less in their public relations effort to denigrate this technological breakthrough and more in their research, development, and innovative imitation.⁸

3. Both Slesinger and the Oxford Group defend the U.S. steel industry against our charge of technological backwardness, asserting that European and Japanese producers did not adopt the oxygen converter and continuous-casting innovations at a significantly more rapid rate.

While it was somewhat extravagant of us (and the trade press) to characterize the foreign installation rate of the new processes as proceeding at a "breakneck pace," we were quite correct in concluding that "both continuous casting and the oxygen process began to be introduced in U.S. steel mills at a significant rate only after the import threat became serious. They were adopted by major mills in the United States at least five years after European mills had recognized them as major cost-saving techniques" [1, p. 647].

The comparative installation rate of the oxygen converter in the United States and abroad speaks for itself. By September 1963, the United States still had only 10.04 million tons of LD capacity in place—compared to 46.21 million tons for the world as a whole [7, pp. 3, 6]. If more than 2.5 million tons of other types of oxygen capacity (Kaldo process and rotary converter) were added to the world total, the U.S. share would have been even smaller. Moreover, the lag of the United States behind foreign steel producers was all the more remarkable, because the LD process developed by the Austrians was *immediately* applicable to conversion of the low-phosphorus ores found in North America. Germany, England, France, Sweden, Belgium, and Luxembourg, by contrast, had to wait until 1957 before the LD process was modified sufficiently (by the addition of lime powders in the LD-AC, OLP and LD-Pompey processes) to be suitable for processing the high-phosphorus ores used in their steel industries. Once this adaptation was made, these countries began to install the latest technology. So did Japan.

The case of Japan puts the issue in focus. By the end of 1960, the Japanese steel industry—which was *one-fifth* the size of its U.S. counterpart and *smaller* than the U.S. Steel Corporation alone—had installed some 5.45 million net tons of oxygen converter capacity, compared to 4.84 million for the United States and *zero* for its largest steel producer [7, pp. 3, 5]. Moreover, in the

⁸ As late as November 1957, U.S. Steel informed the Kefauver Committee that "further development" was necessary before new processes like oxygen steelmaking "conceivably could be substituted for, or displace existing practices." Their "growth potential," the Corporation felt, "cannot be forecast [*sic*]." U.S. Senate, Antitrust and Monopoly Subcommittee, *Administered Prices: Steel, Hearings*, Part 3, 85th Cong., 1st sess., Washington 1958, pp. 1057, 1058. In the same month, however, Jones & Laughlin had already begun operating its "small" 85-ton oxygen converter—with unambiguous success. According to Avery C. Adams, its president and board chairman, "the basic oxygen process represents the only major technological breakthrough at the ingot level in the steel industry since before the turn of the century. With the exception of what we in the industry call trick heats, i.e., one heat made under ideal conditions, the best open hearth practice today results in a production rate of 39 to 40 tons per hour. Our basic oxygen furnaces have produced at the rate of 106 tons per hour to date this month. On a trick heat basis, we have hit 160 tons per hour." Letter to the Stockholders, April 1959.

same year, some 17 per cent of Japanese ingot capacity was in oxygen converters (as compared to roughly 3 per cent in the U.S.) and only 54 per cent in open hearths (as compared to 85 per cent in the United States).⁹ One scarcely need editorialize on these data.

With respect to continuous casting, nowhere are our critics able to rebut the *Iron Age* report that "close to 40 machines were installed [abroad] in the period from 1955 through 1962"; that the U.S. steel industry did not take a "second look" at the process until 1961; and that, except for a pilot plant at U.S. Steel's Chicago Works, the first commercial machine went into operation in the United States in 1962—at the plant of diminutive Roanoke Electric Steel Corporation.¹⁰ As late as September 1965, *Fortune* still reported that "continuous casting of steel was pioneered in Europe but long resisted by U.S. steel makers. Now the resistance is ending."¹¹ Similarly, in August 1965, the Cleveland Federal Reserve Bank stated that "the steel industry in this country has begun to invest in the continuous casting process but it still lags behind Europe where the process has had *widespread* use for *several* years."¹² To suggest that the innovation had to be upscaled before it could be used by the U.S. steel giants is, for reasons cited *supra*, another example of the plant-versus-firm-size fallacy.

The most significant question, of course, is not *how* much the U.S. steel giants lagged technologically but *why*, despite their immense superiority in financial and technical resources, they lagged *at all*—either in invention or innovation, and against far smaller rivals both here and abroad.¹³

⁹ [5, p. 449], Japan Iron & Steel Federation, *Statistical Yearbook for 1961*, p. 25, and Jean Bienfait, *La Sidérurgie Japonaise*, Lausanne: Centre de Recherches Européenne, 1965, p. 89. Incidentally, the Oxford Group's own reference on Japan [10] reinforces our findings: "One of the most impressive features of the Japanese iron and steel industry is the *rapid application* of the LD process and its development to an exceptionally high standard of operating efficiency" [p. 55]. Oxygen converters, according to the report, accounted for only 3.4 per cent of Japanese steel production (as distinct from capacity) in 1957, but for 11.5 per cent in 1960 and 30.7 per cent in 1962 [p. 56]. Comparing the switch from open hearths to converters in Japan and the United Kingdom, the report concludes that "the *pace* of development in Japan is very much more rapid and has taken place much *earlier*" [p. 56]. (Emphasis added throughout.)

¹² "Plant and Equipment Expenditures," *Economic Review*, Aug. 1965, p. 7. (Emphasis added.) For a brief history of invention and innovation of continuous casting, see Jewkes, Sawers, and Stillerman, *The Sources of Invention*, London 1958, pp. 276-80. Note also that the Korotkov study cited by the Oxford Group dealt only with the first year's operation (1955-56) of the continuous-casting plant at the Krasnoye Sormovo Works in the U.S.S.R. On the basis of that (favorable) experience Korotkov predicted that by 1960 "this method of steel casting will augment the output of rolled products [in the U.S.S.R.] by one million tons" and that "two milliard roubles should be saved by using this process" (p. ix).

¹³ The position of the U.S. industry is reminiscent of the lady, interviewed on TV shortly after the Russians launched their sputnik. Asked for her evaluation of the U.S. role in intercontinental and extraplanetary rocketry, she said that "the United States has always been, and always will be, first in everything." When reminded that the

4. All of Slesinger's contentions ultimately rest on his central argument that "so long as steel produced by conventional methods [could] compete with that produced by newer technology, it would not [have been] a wise economic decision to scrap the existing facilities and to destroy vast investments in fixed capital."

Given direct operating savings of about \$5 per ton of oxygen converter over the open hearth; given the investment cost of roughly \$15 per ton of converter capacity (as compared to about \$35-40 per ton of open-hearth capacity), the wisdom of retaining open-hearth facilities should have been questioned in the early 1950's.¹⁴ The precepts of sound replacement economics¹⁵ should have dictated the use of oxygen converters not only for expansion purposes, but also for the wholesale replacement of existing (and presumably serviceable) open-hearth capacity.

But Big Steel chose to ignore these precepts. During the 1950's, it was apparently prepared to live with obsolescent capacity and indulge in its "rational" oligopolistic dislike of any innovation that introduces uncertainty into the pricing process. It was content to let McLouth and Kaiser innovate a revolutionary technology as long as there was no danger that this might precipitate an outbreak of price competition. Relying on its insulation from domestic and foreign competition, Big Steel decided to wait until its technically obsolescent facilities were fully depreciated. Unlike firms in a competitive industry, it was not compelled to regard investment, once made, as truly sunk cost and to take into account only the operating expenses of existing equipment. Instead, it afforded itself the luxury of protecting "vast investments in fixed capital."

Ironically, this protectionism which is the key to the industry's investment decisions during the 1950's and which Slesinger still defends, is currently being subjected to revision, if not reversal, by the industry itself. Its comprehensive modernization program was launched in a period of substantial "unused" (i.e., economically "unusable") capacity. Thus, in 1964 (a banner year for steel), the industry was installing oxygen converters at a brisk pace while using only 75 per cent of existing facilities. Obviously, as the *Wall Street Journal* observed, the increase in ingot capacity came "because of mill efforts to lower costs and not from any lack of raw steel." Indeed, the industry was reportedly mothballing some 7 million tons of open-hearth capacity, reclassifying it as "standby capacity" with the intention of dismantling much of it "be-

Russian satellite and had just beaten us into space, she exclaimed, "Give us time; give us time." In this connection, see our forthcoming article, "Big Steel, Invention, and Innovation," *Quart. Jour. Econ.*, 1966.

¹⁴ *Steel*, Apr. 27, 1959, p. 61; and *The Iron Age*, Dec. 12, 1957, p. 87, and Sept. 24, 1959 pp. 67-68. As early as 1952, a leading trade journal devoted almost an entire issue to a steel conference at Leoben, Austria, where some 360 engineers and scientists (60 of them from 7 countries outside of Austria) met to discuss the oxygen revolution in steel-making and to receive first-hand reports on the experience of the Linz-Donawitz pioneers. These reports dealt with the metallurgical characteristics of oxygen steel, the engineering aspects of operating an LD converter, the economic feasibility of the new process, and a rather detailed statement on operating and investment costs. See *Stahl und Eisen*, Aug. 14, 1952, 72, 989-1024, but esp. 997-1004.

¹⁵ Cf. M. A. Copeland, *Our Free Enterprise Economy*, pp. 181-209.

fore long."¹⁶ According to the *Iron and Steel Engineer*, much of the projected new oxygen capacity will "be used to replace existing workable capacity. Companies are being forced to the process in order to compete. . . . *The low capital cost and the savings in operating costs more than overbalance any considerations to continue operating existing equipment.*"¹⁷ In brief, even the major steel companies now seem to reject the rationalizations of the 1950's as a guide to sound investment decisions in the 1960's.

II

Since there is no main thrust to the diverse criticisms by the Oxford Group, we shall answer them in the order in which they are raised.

1. We are criticized for not assessing the "impact of exogenous causes" on the level of steel imports. But these "exogenous causes" were all reflected in the very existence of an import problem, and it was our purpose to explain the U.S. steel industry's insensitive price behavior in responding to that problem.

2. We are chastised for our lack of concern with the comparative age structure of U.S. and foreign steel plants. Again, this criticism is hardly relevant. Our article dealt with the apparent indifference of the U.S. steel industry to a massive erosion of its home market, and the prevalence of an import-induced two-price system. Indeed, to the extent that the age structure of U.S. steel plants was a significant variable, it should have militated in favor of a prompter counterattack against the import beachheads. Instead, the industry's addiction to target-rate-of-return pricing and cost-plus protectionism of existing investment contributed to its lack of response to steel imports from newer, more efficient foreign plants [1, pp. 652-53, esp. note 19, and our comments on sunk costs, *supra.*].

3. We are challenged on our definition of dumping. Under the Anti-Dumping Act of 1921—the context in which we used the term—an "arithmetic" violation occurs whenever the f.o.b. price in the exporter's home market is higher than his export price (minus transportation costs, customs duties, etc.). The Japanese did not run afoul of the statute, because they met this "arithmetic" requirement. They did not absorb freight between Yokohama and Pittsburgh. They practiced neither dumping nor charity—in a legal or economic sense—but they *were* guilty of waging competition against an exploitative oligopoly.

4. Our critics fail to understand why independent fabricators continued to buy 50 per cent of their wire rod from domestic producers at prices higher than those charged by importers. The reason (given by the fabricators) is simple, viz. "in order not to cut themselves off from domestic supply sources" [1, p. 645]. And this is not as irrational as the Nuffield College economists imply. Maintaining good will is important in an industry that suffers from periodic shortages of domestic supply and where such political vagaries as tariff manipulation make a total reliance on foreign sources risky, if not foolhardy.

5. The Oxford Group questions the value of our analysis because it rests on

¹⁶ Jan. 4, 1965, p. 4.

¹⁷ Jan. 1963, p. 171. (Emphasis supplied.)

"a wholly atypical product" like wire rod. This statement borders on the preposterous. Between 1957 and 1962, wire rod was one of the industry's largest tonnage imports, and increased faster than the imports of any other steel product. It was the keystone for an entire segment (wire and wire products) of the steel industry. It captured a sizable share of the noncaptive U.S. market—17.1 per cent as early as 1958, 39.2 per cent in 1962, and more than 40 per cent since 1963 [1, p. 631]. Finally, the PEP pamphlet on *Steel Pricing Policies*, which the Oxford Group cites with approval, itself singles out wire rod to illustrate typical price fluctuations in world markets.¹⁸

6. Our vertical integration hypothesis is said to lack generality because "among the great bulk of steel products which are imported, the majors did not have to worry about price competition in other markets from their customers." Aside from the lack of substantiation for this claim, our critics simply reiterate and support—while seeming to refute—our explanation for price behavior in the "wire rod-wire products" segment of the steel industry. Yet they insist, with inexplicable fervor, that our vertical integration hypothesis does not apply to those segments of the industry where there is no vertical integration or dual distribution. They seem unwilling to take cognizance of the subject matter dealt with in our article, and rather accurately described in its title, "Steel Imports and Vertical Oligopoly Power." (Emphasis added.)

7. Our critics suggest that "there are many reasons why the U.S. industry might not have met [import] competition with price reductions aside from vertical integration." But here they seem to ignore the differences between rational behavior in a horizontal and vertical context. If the steel industry were organized in the form of successive horizontal oligopolies, the import phenomenon would clearly have had a different impact. At each stage, the horizontal oligopolists would have greeted substantial imports in the same manner as they would the appearance of a nonconformist price cutter [1, p. 653]. They would have been compelled to regard the market for each product as a separate (i.e., the only relevant) market in order to make rational pricing decisions.

8. Our critics tell us that the U.S. steel industry is a multi-product industry, and hence enjoys production flexibility—i.e., the possibility of shifting from "unprofitable" items facing import competition to "profitable" items, presumably insulated from such competitive threats. But they offer no evidence whatsoever that the steel industry during this period availed itself of this production flexibility, and that it in fact compensated for the loss of import markets by shifting to more profitable items. Throughout this period, there was substantial and persistent overcapacity in all segments of the industry, and especially in basic steel.

9. We are said to be misled in our "view that oxygen conversion was adopted sufficiently more quickly by competing foreign steel firms to give them a significant cost advantage." Nowhere did we make such a statement, nor was our vertical integration hypothesis dependent on such a cost-anchored comparison. Nevertheless, the technological backwardness of the U.S. steel in-

¹⁸ P. 345. See also Council of Economic Advisers, *Report to the President on Steel Prices*, Washington, April 1965, pp. 14-15.

dustry could not be ignored in view of the industry's addiction to target-rate-of-return pricing, its refusal to regard capital costs as sunk costs, and its insistence on recouping investment—come what may, and *coute que coute*. In this context, technological backwardness meant that the industry was imprisoned by its higher book costs associated with past investment, and hence unwilling to meet the import threat with aggressive price competition. It thus reinforced the insensitive price behavior that was an outgrowth of vertical integration.¹⁹

III

After careful evaluation of the criticisms from Pittsburgh and Oxford, we are still not persuaded that the U.S. steel industry is technologically progressive, or that vertical integration *cum* dual distribution is an unimportant determinant of steel pricing policy.

WALTER ADAMS AND JOEL B. DIRLAM*

*The cost implications of technological backwardness are also noteworthy, of course, in view of the traditional assumption that *superior* technology enabled U.S. steel firms—despite the handicap of higher wages—to compete successfully in world markets. Perhaps, as one cynic remarked, the failure of the industry to be *au courant* of the latest technology is attributable to the consistently moderate demands of the United Steel Workers of America.

*The authors are professors of economics at Michigan State University and the University of Rhode Island, respectively.

Manufacturing Investment, Excess Capacity, and the Rate of Growth of Output: Comment

In a recent article in this *Review* [1, p. 607] Professor Alice Bourneuf states, "This paper tests the accelerator in a period during most of which there was little or no pressure on capacity." And also that "accelerator-type forces may be more important in periods of pressure on capacity." The purpose of this comment is to attempt to clarify the extent to which these propositions have in fact been tested.

Consider the relationships between capacity (C_t), desired output (\bar{Y}_t), and desired capital stock (\bar{K}_t), where capacity is defined in an accounting

sense and is the maximum output which could be produced given the capital stock. Typically desired output is less than capacity:

$$Y_t = rC_t \quad \text{where } 0 < r < 1.$$

Then we may define (1) the capital-output ratio or conventional accelerator as $\sigma = \bar{K}_t/Y_t$, and (2) a capital-capacity ratio as $\sigma_c = K_t/C_t$. It follows that $r\sigma = \sigma_c$ so that in general the conventional accelerator is larger than the capacity accelerator.

Now, given the form of Miss Bourneuf's investment equation [1, p. 609],

$$(1) \quad I_t = a(C_{t-1} - Y_{t-1}) + bC_{tt} + c\Delta Y_t + k$$

and considering only the first term, if we let $a = -\beta\sigma_c$, then substituting we get

$$\begin{aligned} (2) \quad a(C_{t-1} - Y_{t-1}) &= -\beta\sigma_c(C_{t-1} - Y_{t-1}) \\ &= -\beta K_{t-1} + \beta\sigma_c Y_{t-1} \\ &= \beta(\sigma_c Y_{t-1} - K_{t-1}), \end{aligned}$$

which is a more recognizable form of the acceleration principle with adjustments for capacity considered where β is the reaction coefficient. However, the accelerator is not the conventional capital-output ratio but rather the smaller σ_c .

Miss Bourneuf's coefficient a embodies both β and σ . Indeed, this is clear since after a is estimated in the study it is divided through by an assumed capital-output ratio (σ), so that the reaction coefficient β may be determined. Similarly, one might have estimated the accelerator by dividing a by an assumed β . The estimates of β , then, are reasonable only to the extent that the assumed accelerator is reasonable. The difficulty here is obvious. Separate estimation of β and σ is desirable, and their joint determination, as in this case, makes it difficult to infer the magnitude of either. In addition, dividing through by σ rather than σ_c will result in underestimating β . Finally, the need to divide through by a capital-output ratio removes much of the apparent empirical advantage of using capacity figures rather than capital stock estimates.

When measuring the accelerator using capacity data the distinction between capacity in the accounting sense (maximum output) and capacity in the economic sense (minimum cost) must be kept in mind. A logically consistent accelerator formulation using accounting capacity as a variable is either

$$I_t = \beta(\sigma r C_{t-1} - K_{t-1})$$

or

$$I_t = \beta\sigma(rC_{t-1} - Y_{t-1}) + (1 - \beta)I_{t-1}.$$

These are equivalent [2, p. 187], and the second form which is based on a distributed lag assumption would enable simultaneous estimation of β and σ .

The second term of equation (1) is straightforward. If ρ is the rate of depreciation, then $b = \rho\sigma_c$ and the true depreciation rate is determined by

dividing b by σ_c . Since b was actually divided by σ , ρ may be underestimated.

The coefficient c in the third term is more difficult to interpret. Alone it would be a simple accelerator coefficient. However, since the accelerator is part of coefficient a in the first term, this cannot be the case. It is not, then, surprising that the value of c is so small. (It is not significant at the .05 level in six of the 13 equations, and in two of these it has the wrong sign.) One might suspect that ΔY_t was added rather as an afterthought to soak up residual variance. In any case, a reasonable theoretical interpretation is not obvious. Empirically, one can say that, other variables having been considered, a \$1 increase in Y leads to \$.15 more I . However, when the coefficient is divided by σ , the very limited interpretation becomes quite apparent, e.g., if the capital stock is increased by \$1, investment rises by \$.09. Obviously the coefficient does not mean what it says. If c were an accelerator coefficient, then dividing it by σ would yield a value of approximately 1. In fact it is rather a kind of residual accelerator picking up the variation after the first term ($C_{t-1} - Y_{t-1}$) has been considered. The statement in the text, "manufacturers plan to expand capacity up to only 9 per cent of the addition to output" [1, p. 621], is certainly misleading if not incorrect. Miss Bourneuf goes on to state:

Direct effects of output changes are small, but it must be remembered that additions to output decrease excess capacity, and therefore increase investment, and that higher investment increases total capacity, and therefore in turn leads to more replacement investment, but also more excess capacity [1, p. 621].

This quotation highlights the difficulty of interpreting the coefficients. The accelerator, while only part of coefficient a , is more than coefficient c . The presence of c may actually bias a downwards since at least some of the accelerator impact is contained in c . If this is the case, then the estimates of β , the reaction coefficient, may similarly be biased downwards. Thus it does not seem that there has been a test of the acceleration theory of investment or that there is evidence presented on the varying importance of the accelerator depending on capacity. To show that excess capacity is an important determinant of investment is not necessarily to test the acceleration principle.

Manufacturing Investment, Excess Capacity, and the Rate of Growth of Output: Reply

Professor Houston raises a basic question on the reasonableness of my equations and also some relatively minor technical points.

I agree that my equations test a capital-capacity accelerator rather than a capital-output accelerator; since induced investment is for the purpose of adjusting capacity, this seems to me to be a reasonable accelerator concept.

Houston also suggests that in strict logic the adjustment of the coefficients of the capacity terms in my equation to a capital stock basis should have been by a capital-capacity ratio rather than a capital-output ratio, since "desired output" is smaller than capacity. He defines capacity "in an accounting sense . . . as the maximum output which could be produced given the capital stock." The capacity indexes I used probably reflect maximum output under normal operating standards, usually referred to as an engineering concept of capacity. Houston's "desired output" is determined by cost factors; this concept may be roughly reflected in the preferred operating rates reported at times to McGraw-Hill, which have ranged from 90 to 98 per cent of capacity. The capital-output ratios I used were based on data for years of very high operating rates in many industries, and the use of capital-capacity estimates would have raised the coefficients, as adjusted, at most by roughly 10 per cent. This might have been a preferable procedure. Using estimates of capital-output ratios to adjust the coefficients of both the output and capacity terms was a very rough procedure, perhaps not too bad in view of the uncertainties on the absolute levels of the capital stock and capacity estimates.

Houston's basic criticism is that my equations do not fit conventional forms of the acceleration principle; in particular a capacity form, which is equivalent to a distributed-lag form, assuming expected output to be some constant times output in $t-n$, or a weighted average of past periods' outputs, a lag of some sort in the investment process of n periods, and geometrically declining weight for past changes in output in the distributed lag form. I agree that my equations are not consistent with these precise models, but I believe they are reasonable.

My equations assume that this year's change in output affects the expected future level of output, and, therefore, investment, and that the lagged excess capacity term exerts an independent dampening influence on investment.¹ Past changes in output affect investment through their effects on the excess capacity term; they clearly affect last year's total output, and they also affect last year's total capacity via their effects on investment in previous years. They also affect investment through the capacity term designed to catch replacement.

My investment and capacity equations together can be solved to make investment a function of all past changes in output, weighted in some complex

¹ The current period change in output term seems to me to be much more important in an annual model than it would be in a quarterly model. I also suspect that certain simple distributed-lag schemes are more suitable for explaining quarterly investment because they can be interpreted as reflecting gestation-period effects.

fashion. It is this fact that I was trying to express in the sentence Houston quotes as misleading or mistaken. The iteration examples I worked out actually trace this process over time. Together my equations can be made equivalent to some sort of distributed-lag principle. But the behavior of investment is not believed to be explained by a series of lagged reactions to changes in expected output based on past changes in output.

Since the excess capacity term in my equation does not by itself represent the difference between desired and actual capacity, Houston's suggestion that the speed of reaction coefficient be estimated from the data on the basis of a simple distributed-lag function, with weights of past output changes declining geometrically, cannot be accepted.

My equations imply that the effects of the excess capacity and current change in output terms are additive. The c coefficient of the change in output term probably is related functionally in some fashion to the a coefficient of the excess capacity term; the results for various industries suggest this is the case. The precise nature of this relationship is not clear, however, and separate estimation of the coefficients seems to be a legitimate procedure.

Houston does not think I have tested the acceleration principle. Perhaps this is a matter of definition. I think of the acceleration principle as stating that investment is positively related to output and negatively related to capital stock or capacity. My equations are a test of the acceleration principle in this sense.

A Note on Progression and Leisure: Comment

In a recent communication, Robin Barlow and Gordon Sparks [1] attempt to overthrow one of the oldest and most respectable conclusions in public finance theory, namely that an individual will choose to work fewer hours if a proportional income tax is replaced by a progressive income tax of equal yield.¹ On the basis of a brief reappraisal of the familiar geometrical analysis made by Kenneth Boulding [2, pp. 773-75] and set out in rather more detail in Richard Musgrave's treatise [4, pp. 241-43], the authors suggest that there is nothing in the conventional diminishing marginal utility assumptions which logically excludes the possibility that a mildly progressive tax will induce a greater supply of effort than an equal-revenue proportional tax. The conditions under which this "neglected outcome" is possible are then deduced by means of a mathematical analysis of the orthodox model. As a result of this

¹ The authors concede that if "equal yield" is defined in the way suggested by Otto von Mering [5, pp. 454-55], the traditional conclusion holds without modification. Under this definition a progressive tax is said to be of equal yield if, *with the individual working the same number of hours as under the proportional tax*, the revenue raised would be the same. Barlow and Sparks refer to this as an *ex ante* definition of equal yield. Why the government should be so naïve or eccentric in its conception of equal yield is, however, unclear. It seems better to recognize that the comparison suggested by von Mering is for most purposes arbitrary and irrelevant.

analysis they conclude that the traditional result requires qualification to the extent that "*when the marginal utilities decline slowly, a mildly progressive tax with rates substantially lower than that of the proportional tax may produce an equal yield as a result of inducing more work effort*" [1, p. 377]. Although they do not mention it, their analysis would also overthrow the closely related and equally well-known welfare conclusion that the "excess burden" imposed on an individual by a progressive income tax is necessarily greater than that imposed by an equal-revenue proportional tax.² Regarding the practical importance of their dramatic modification of the traditional view the authors are, however, extremely cautious, and suggest that "The circumstances which give rise to this neglected result are of doubtful realism. . . . For all practical purposes the theorem remains valid . . ." [1, p. 377]. Few of their readers can have felt so sanguine. Is it really so unlikely that "marginal utilities decline slowly"?

It is the purpose of this note to show, by means of a careful re-examination of the conventional geometrical analysis, that the Barlow and Sparks result, though technically correct, is of negligible practical interest for reasons completely unrelated to the rate of decline of the marginal utilities. Thus we shall find that their proportional-progressive tax comparisons are in general irrelevant. When appropriate alternatives are compared, the familiar result holds without qualification. The single-individual case considered in the conventional analysis (and by Barlow and Sparks) is, however, extremely unrealistic; for practical purposes we are interested in the group. Again comparing relevant alternatives, we find that the familiar result for the single-individual case need not hold for the group.

I. The Single-Individual Case

The conventional analysis considers the case of a *single individual* free to choose between leisure and income, both assumed to be subject to diminishing marginal utility. In Figure 1, pre-tax opportunities are represented by A_0B_0 with the individual in equilibrium at X_0 , where indifference curve i_0 is tangent to A_0B_0 . The effect of a lump-sum tax of amount A_0A_1 is to establish a new equilibrium at X_1 on the new opportunity line A_1B_1 parallel to A_0B_0 .

If the government attempts to raise the same revenue A_0A_1 by means of a proportional income tax, the net wage rate to the individual is reduced. In the familiar geometrical exposition it seems to have been assumed that the

² Indeed their analysis suggests the need for a similar revision of accepted views regarding the positive and welfare effects of more and less progressive income taxes, not only on the supply of effort, but also on the supply of savings and risk-taking. The results of our re-examination of their findings with respect to effort can be applied *mutatis mutandis* to the other cases also.

In these simple cases it is of course assumed that supply is perfectly inelastic for all factors except the one under consideration. Where more than one factor is elastically supplied, the analysis becomes more complicated, and the results we shall obtain for the single-individual case need no longer hold. The reasons for our agnosticism in the case of the group are also correspondingly reinforced.

FIGURE 1

rate of proportional tax, and hence the position of the proportional tax opportunity line, is uniquely determined by the requirement that the post-tax line should be tangential to an indifference curve on the equal-revenue locus A_1B_1 . In general, however, this is obviously not the case. The diminishing marginal utility assumptions in no way exclude the possibility that there may be several different proportional tax rates (and opportunity lines) all producing the same revenue A_0A_1 .³ Thus, when very conventional Hicksian assumptions regarding the shape of the "price-consumption" curve $X_0X_2X_3B_0$ generated by continuous variation of the proportional tax rate are made, it is apparent that the required revenue A_0A_1 can be raised by either of the two proportional taxes represented by opportunity lines A_2B_0 and A_3B_0 .⁴

The price-consumption line $X_0X_2X_3B_0$ divides the equal-revenue locus into three segments, A_1X_2 , X_2X_3 , and X_3B_1 . At points between A_1 and X_2 it follows from the diminishing marginal utility assumptions and the shape of the price-consumption line that indifference-curve slopes are everywhere

³ Essentially the same point, however, has been quite widely recognized in the analysis of excise taxes. In fact, of course, the "income" tax, as conventionally interpreted and applied, is precisely an excise tax on effort. If income is interpreted more broadly to include an imputed value for leisure, the price effects we are considering disappear.

⁴ It is interesting to notice that Musgrave's diagram [4, p. 242] includes a price-consumption line of precisely this sort. However, he overlooks or ignores the proportional tax alternative corresponding to our A_2B_0 .

less than the slopes of the corresponding proportional tax lines. Let us now consider the possibility suggested or at least implied by Barlow and Sparks that a progressive tax opportunity line with slope less than that of A_2B_0 may produce equilibrium at some point X_4 below X_2 (though presumably above X_1) on A_1B_1 ; in other words, that there may be a mildly progressive tax more stimulating to effort than the proportional tax represented by A_2B_0 , and yielding the same revenue A_0A_1 . Following the simple mathematical model of Barlow and Sparks, we shall assume that the progressive tax takes the form of a proportional rate applied to income in excess of an exemption; this in no way restricts the generality of the argument. Let us suppose then that the progressive tax opportunity line is $A_4X_4C_0B_0$, where the slope of A_4C_0 is less than that of A_2B_0 . Is progressive tax equilibrium possible at X_4 ? To see that it is *not*, consider the proportional tax line A_5B_0 passing through X_4 . From our particular assumptions regarding the indifference map (and reflected in the shape of the price-consumption curve $X_0X_2X_3B_0$), proportional tax equilibrium at X_4 is impossible because the slope of the proportional tax line A_5B_0 exceeds that of the corresponding indifference curve at X_4 . However, the slope of the progressive tax line $A_4C_0B_0$ is necessarily greater than that of A_5B_0 , and equilibrium in the progressive tax case is therefore a fortiori *impossible*.

Consider next the possibility of progressive tax equilibrium in the range X_2X_3 . At points between X_2 and X_3 , indifference-curve slopes are everywhere greater than the slopes of the corresponding proportional tax lines. Is it possible that a progressive tax opportunity line such as $A_6C_1B_0$ with slope less than that of A_3B_0 may produce equilibrium at some point X_5 below X_3 (but above X_2) on A_1B_1 ; in other words, that there may be a mildly progressive tax more stimulating to effort than the proportional tax represented by A_3B_0 ? Consider the proportional tax line A_7B_0 passing through X_5 . From the price-consumption curve $X_0X_2X_3B_0$ and the diminishing marginal utility assumptions, it is clear that at X_5 the slope of the indifference curve is greater than that of A_7B_0 . The slope of the progressive tax line $A_6C_1B_0$ necessarily exceeds that of A_7B_0 , and progressive tax equilibrium is therefore possible at X_5 .⁵ For taxes with the right degree of progression, it is clear that progressive tax equilibria can be established at all points between X_2 and X_3 . In general there will therefore be an infinite number of progressive tax schedules more stimulating to effort than the proportional tax represented by A_3B_0 .

⁵ It is interesting to notice that Musgrave's progressive tax opportunity line is drawn to produce equilibrium in a range corresponding to our X_2X_3 . He does not, however, demonstrate that such an equilibrium is in fact possible, nor does he remark upon its significance for the theorem he is attempting to prove. Even more important, he fails to show that progressive tax equilibrium could not equally well be established in a range corresponding to A_1X_2 . His "proof" [4, p. 241, n. 1] serves only to establish the possibility of progressive tax equilibrium somewhere in the range X_2B_1 . Boulding [2], and Alan Williams [8, pp. 65-68] who follows his treatment very closely, offer no formal proof whatever. In a note published shortly after the rigorous analysis by Barlow and Sparks, Malcolm Levitt [3] provides a clear statement but no formal proof of the Barlow-Sparks result, and similarly implies, but does not prove, the impossibility of progressive tax equilibrium in our range A_1X_2 . He apparently fails to see the significance of the latter result.

Indeed, considering the segment X_1B_1 , it is easy to see that there is no progressive tax as depressing to effort as the proportional tax represented by A_1B_0 .

In the above argument we have made only the simplest Hicksian assumption regarding the shape of the price-consumption curve. In general there is no reason why the number of intersections with the equal-revenue locus, and hence the number of proportional tax alternatives, necessarily need be restricted to two.* Thus, for certain levels of revenue, the price-consumption curve may divide the equal-revenue locus into a number of additional segments having similar characteristics to A_1X_2 and X_2X_3 . Progressive tax equilibrium will then be impossible in segments corresponding to A_1X_2 where indifference-curve slopes are less than proportional-tax slopes, and possible in segments corresponding to X_2X_3 where indifference-curve slopes are greater than proportional-tax slopes.

As a result of this analysis we can conclude that, in the conventional framework, there will in general be many progressive income tax schedules more stimulating to effort (and imposing a smaller excess burden) than at least one proportional tax of equal yield. It is certainly true, as Barlow and Sparks suggest, that this result has been widely overlooked or ignored in the public finance literature; and, contrary to Barlow and Sparks, there seems no reason whatever to suppose that the circumstances which give rise to it are in any sense unrealistic.

More important, however, is our finding that in the case of the single individual there is no progressive tax schedule capable of producing as much work effort (or imposing as small an excess burden⁷) as the "best" (or least burdensome) proportional tax yielding the same revenue. In their analysis Barlow and Sparks completely overlook the crucial possibility that the revenue produced by their proportional tax CB/OB might alternatively have been produced by a lower-rate proportional tax more stimulating to effort. In fact, however, it is only where such a lower-rate alternative actually exists that their argument [1, Sec. III] regarding the existence of a more stimulating progressive tax can possibly be valid.⁸ Similarly in their mathematical model it can readily be shown that $ds/de < 0$ (for $e = 0$) only where $ds/dt > 0$, viz., where $\eta_w < t$ (s being leisure, e the exemption level, t the rate of proportional tax, and $-\eta_w$ the elasticity of the marginal utility of

* In particular cases there may of course be only one, or even none, depending upon the amount of revenue to be raised. In the former case the price-consumption curve will be tangential to A_1B_1 at a single point, and the revenue raised will be a maximum for the family of proportional taxes. Here there will be no progressive tax capable of raising the given revenue A_1A_1 . It is also conceivable that there may be several proportional taxes capable of raising the maximum revenue for the proportional tax family. For this level of yield there will again be no equal-revenue progressive tax for purposes of comparison. See Pigou [7, Pt. II, Ch. 5].

⁷ Even in the case of a single individual, the conclusion regarding excess burden is generally valid only if there are no other taxes already in existence.

⁸ In this case, however, their argument [1, Sec. II] regarding the possibility of a less stimulating progressive tax is necessarily invalid if we assume a conventional Hicksian price-consumption curve.

income schedule); in other words, that an equal-revenue progressive tax can stimulate more effort than a given proportional tax only where there are other equal-revenue proportional taxes (at lower rates) more stimulating to effort than the one under consideration. For the best proportional tax, $ds/dt > 0$ is ruled out, and $ds/de < 0$ is therefore impossible. It could reasonably be argued, however, that for relevant comparisons, only the best proportional tax should be considered.⁹ Why should the government consider imposing a high and extremely burdensome rate of proportional tax if the same (or even a greater) revenue can be raised less painfully by imposing a lower rate? If this argument is conceded, it is clear that the traditional result, properly formulated, holds without qualification.

Regarding the more general question as to the relative effects of more and less progressive (or regressive) income taxes, of which the problem we have been considering is merely a special (and very simple) case, we can show, using a similar geometrical approach, that if the degree of progression of a tax family remains constant over all ranges of income, the best member of a more progressive family necessarily reduces effort more and imposes a greater excess burden than the best member of a less progressive family. If the degree of progression varies over different income ranges, only the conclusion for the special case we have been considering necessarily still holds.¹⁰

II. *The Group Case*

For practical purposes, however, we are interested in effects on the community rather than the single individual. As it stands, the conventional analysis of the single-individual case tells us nothing about this more important question. It might, however, be suggested that if the substitution of the best progressive income tax for the best proportional tax of given revenue necessarily reduces effort in the case of a single individual, the effect of making this same substitution for each and every individual must surely be to reduce work effort (and welfare) of all individuals and hence total work effort (and welfare) for the community.

This generalization to the group which follows naturally from the form of the traditional analysis, though formally unobjectionable, is, however, notoriously misleading. In general, the only way in which such a substitution could be made in the income tax field would be by applying different progressive rate schedules to all individuals, these schedules being so designed as to impose the same total liability on each individual as under the given proportional tax. Such a procedure is obviously administratively impossible and politically unacceptable. Moreover, the main reason for considering the progressive

⁹ At the other end of the spectrum of relevance, the fact that there is no progressive tax so burdensome and depressing to effort as the "worst" proportional tax is clearly of no conceivable practical interest if, as seems reasonable in this context, we can abstract from "merit wants" or sumptuary considerations.

¹⁰ For purposes of this more general analysis the degree of progression can be defined in a number of ways, all yielding the same results. Pigou [7, Pt. II, Ch. 2] distinguished two possible measures, the rate of change in the average tax rate and the rate of change in the marginal tax rate. These and other possible definitions are discussed by Musgrave and Tun Thin [6].

tax alternative in practice is of course that it provides the obvious means of imposing relatively higher average rates of tax on the higher-income groups. The progressive tax substitution envisaged above could not, however, perform this function, but simply represents a diabolically complex method of imposing the constant average rate of the proportional tax.¹¹ In general, and with relatively minor modifications, it therefore seems necessary, for comparisons of even the slightest practical relevance, to consider substantially the same rate schedule applied to all individuals.

However, if the same rate schedule must be applied to all individuals, it is only if leisure-income tastes and opportunities are identical that the familiar results will still hold.¹² In the more relevant and realistic case where tastes and opportunities may vary widely, no sweeping generalization is possible. The substitution of the best progressive tax for the best proportional tax will raise marginal and average rates of tax to high-income individuals, and lower them to low-income individuals, whilst some middle-income recipients will pay higher marginal and lower average rates. Given only the conventional diminishing marginal utility assumptions, the net effect on the supply of effort, both for the higher and lower income groups and for the community as a whole, is obviously impossible to predict.¹³ A similar agnostic conclusion holds also for welfare effects on the community.¹⁴

¹¹ If the reason for considering the progressive tax alternative is (say) built-in flexibility, this particular objection does not hold. The equal-revenue requirement must then of course be interpreted as applying "over the cycle."

¹² As emphasized in the pioneering contributions of Earl Rolph and George Break [5, pp. 110-22], and Ian Little [5, pp. 123-31], the simple geometrical analysis of the effects of taxation on a single individual, which we have applied to the leisure-income choice in Section I above, cannot be used to derive results applicable to the group. For the latter purpose the opportunity lines of the single-individual analysis must be replaced by the corresponding transformation curves, and the "given revenue" must be interpreted in terms of a given resource transfer to the public sector. Rolph and Break went on to show that the familiar Hicks-Joseph proposition regarding the "excess burden" of an excise as compared with an income tax, previously "demonstrated" with the aid of the single-individual diagram, necessarily holds for the group only if perfect pre-tax allocation is assumed. Little then demonstrated that, even if perfect pre-tax allocation is assumed, the proposition is still not generally valid unless factor supplies are perfectly inelastic.

Applying this general equilibrium methodology to our present comparison of the effects of proportional and progressive income taxes on leisure-income choice (with fixed quantities of other factors), the simple diagram of Figure 1 can readily be modified along Rolph-Break lines to incorporate a leisure-commodity transformation schedule of the familiar convex variety. Then, assuming perfect pre-tax allocation and a "world of equals," the proposition that the best proportional tax produces more effort and imposes a smaller excess burden than the best progressive tax securing the same resource transfer to the public sector can still be illustrated geometrically even in the case of a group. However, in this world of equals the main practical reason for considering not only the progressive tax alternative but any form of income taxation would have disappeared. A nondistorting lump-sum tax such as the poll tax becomes distributionally unobjectionable!

¹³ This point has been clearly recognized and developed in some detail by Musgrave [4, pp. 243-46].

¹⁴ The reason is, however, rather different, since the differential income effects of the progressive tax, which may be of great importance in the positive analysis, are irrelevant from the point of view of efficiency.

III. Conclusions

On the basis of the above discussion, it appears that the Barlow and Sparks analysis requires modification or clarification in a number of important respects. (1) In the conventional case of a single individual, there will in general be many progressive income taxes more stimulating to work effort and imposing a smaller excess burden than at least one proportional tax yielding the same revenue to the government. The circumstances giving rise to this result are in no way unusual or unrealistic. (2) As a rule, however, there seems no reason to suppose that the government will include these inferior (and higher-rate) proportional taxes in its comparisons. Concentrating on relevant alternatives, we find for a single individual that the best proportional income tax necessarily produces more work effort and imposes a smaller excess burden than the best progressive income tax. This is in fact precisely the formulation of the traditional result to be found in Pigou's classic study [7, Pt. II, Ch. 5]. (3) The single-individual case considered in the conventional analysis is, however, of negligible interest in itself, and extremely misleading in its apparent implications for the group. In the general case of a community of individuals with varying tastes and leisure-income opportunities, the effects, both on the supply of effort and on excess burden, of substituting the best single progressive rate schedule for the best single proportional rate schedule are impossible to predict. Thus for reasons very different from those implied by the Barlow and Sparks analysis, the simple theory we have been examining suggests no weighty objections to progressive income taxation from the point of view of announcement effects on the supply of effort. Here again it is salutary to notice that the classic formulation of Pigou remains unexceptionable [7, Pt. II, Ch. 6].

A Note on Progression and Leisure: Reply

As far as the technical aspects of Head's contention are concerned, we are in agreement that our condition for an increase in work effort as a result of replacing a proportional tax by an equal-yield progressive tax can hold only if there exists a lower rate proportional tax with the same yield. This is clearly demonstrated by his geometrical exposition, although his interpretation of our mathematical model is not clear. The question at issue is whether, given an initial proportional tax rate which satisfies the equilibrium conditions stated in our equations (2), (3), and (4) for a given yield and a zero exemption level,¹ there exist other values of t which also satisfy these equations. This question cannot be answered simply from the sign of the derivative ds/dt . A rigorous condition can be derived by observing from Head's diagram that a lower rate equal-yield proportional tax will exist if, and only if, the falling price-consumption curve cuts the equal-yield line from above at the initial equilibrium point; that is, if, and only if, the slope of the price-consumption curve is greater (in absolute value) than the slope of the equal-yield line at the initial equilibrium point. This condition can be shown to hold precisely under the circumstances specified by our inequality (12).²

As for the practical importance of our result, we feel that Head overstates his case. His contention that a comparison between a progressive tax and the "best" proportional tax is "appropriate," "valid," and "relevant," whereas other comparisons are "irrelevant," is essentially arbitrary if one is concerned with predicting the effect of tax changes on the supply of effort rather than the welfare implications of different taxes. In a real situation, it is not self-evident that the tax which is to be replaced will be the "best" of its family.

Head is correct in saying that the case of the group, as analyzed by Musgrave, is of more practical interest than the case of the individual. Nevertheless our concentration on the individual was deliberate, since after Musgrave's treatment of the group, the case of the individual remained as the only theoretical case which allegedly "proved" that progression necessarily reduces work effort.

ROBIN BARLOW AND GORDON R. SPARKS*

¹ See Robin Barlow and Gordon R. Sparks, "A Note on Progression and Leisure," *American Economic Review*, June 1964, 54, p. 376. We would like to take this opportunity to correct two minor typographical errors in our original communication. Equation (2) should be

$$y = (1 - t)x + e$$

and Equation (5) should be

$$\frac{dy}{de} + (1 - t)w \frac{ds}{de} + x \frac{dt}{de} = t.$$

Diminishing Returns and Linear Homogeneity: Further Comment

It is with considerable interest that we read the different communications on "Diminishing Returns and Linear Homogeneity" that appeared in this *Review* (September 1964). Those of Dr. D. Schneider and Professor G. Warren Nutter retained our special attention. Unfortunately both the communications, otherwise ably written, contain serious mistakes when they treat the cases of the so-called Law of Diminishing Returns in the history of economic analysis. Of the two, Dr. Schneider's note is much more explicit on this point.

I

Dr. Schneider speaks of the "traditional law of diminishing returns" without, however, explaining clearly what he means thereby. If he means thereby the law "promulgated" by Serra and Turgot to which Knut Wicksell later subscribed, as he seems to imply (and in which Nutter seems to concur), he is guilty of half-truths. In the first place, Serra [4, pp. 23 ff.] is much more explicit on the so-called increasing returns from industries than on diminishing returns from agriculture, on which a clear and unambiguous statement from him is not easy to come by. Turgot's statement on the law of returns is, on the other hand, a marvel of rigour and precision.

As a matter of fact, if we are to speak at all of the "traditional law of diminishing returns" we must begin with its first explicit formulations by Turgot and West. Their formulations are, however, quite different. As we shall try to show presently, in modern economic analysis F. Y. Edgeworth and Wicksell are respective continuators of Turgot and West.

II

West [7, p. 12], unlike Turgot, constantly confuses between diminishing average returns and diminishing marginal returns and, unlike Turgot again, supposes diminishing returns to operate from the very beginning of the incremental application of the variable input. If we compare this with Wicksell's position [8] we find a close similarity between the two. In one place Wicksell speaks of the "decline in the average yield of labour when the number of labourers is increased" and he qualifies this as the "law of diminishing returns" [8, p. 122]. Elsewhere he speaks of the "law of variation of the total product of a given area, when the number of labourers and the intensity of agricultural work increases or decreases," and the numerical example he gives shows the case of diminishing marginal returns [8, p. 114]. Moreover, he maintains that "the law presumably operates from the beginning" [8, p. 123]. In all this Turgot's position [6] is quite different. Indeed his performance in this respect is of such high order that it remained for Edgeworth [1] only to give finishing touches to it and thereby render it technically more perfect. In fact, contrary to what Schneider and Nutter think, it is not Wicksell but Edgeworth who should be more justly bracketed with Turgot in this respect.

First, in the two input-one output case Turgot [6, p. 645] states what in effect is the law of variability of *marginal* and not of *average* returns to the

successive increments of the variable input, the other input remaining constant. This is exactly what Edgeworth [1, p. 67] calls the "primary concept" of diminishing returns.¹ Secondly, with Turgot [6, p. 644] again, as it is later with Edgeworth [1, p. 70], the diminishing returns are a criterion of a maximum. Finally, Turgot [6, p. 645] holds that there is first a phase of *increasing* marginal returns before *diminishing* marginal returns set in. Edgeworth's position [1, p. 68] again is basically similar. In other words, in the Turgot-Edgeworth case the graph of the (supposedly) differentiable output function (with respect to the variable input) is at first convex and then concave from below, whereas in the West-Wicksell case it is concave from the beginning. Moreover, Schneider's assertion that "there is a positive output even when no variable input is used" may be true for Wicksell but it is hardly true for Turgot [6, p. 645], who explicitly holds that "seed thrown on a soil naturally fertile but *without any preparation* would be an advance *almost entirely lost*";² which means that land is what Karl Menger [3, p. 37] calls in his now classic article a "dependent input" (*Unselbständiges Gut*), i.e., with l as land-input and $l > 0$, we have $f(l, 0) = 0$. Thus, unlike Schneider, we do not see any contradiction between the Turgot-Edgeworth case and the Knightian case [2, p. 99].

PARESH CHATTOPADHYAY*

*The author is lecturer in economics at the Institut d'Etude du Développement Economique et Social of the University of Paris. He expresses his gratefulness to Professor E. Malinvaud, who kindly went through an earlier draft and suggested a number of improvements.

¹ Thus G. Stigler [5, p. 112] is misleading when he asserts that the average and marginal returns "had been used as synonymous since the very discovery of the law of diminishing returns."

Diminishing Returns and Linear Homogeneity: Further Comment

The interesting exchange between Liebhafsky, Sato, Rowe, Schneider, de Fontenay, and Nutter in the September 1964 issue of this journal leaves one loose end which proves both embarrassing and challenging. If they are correct, as undoubtedly they are, in their assertions as to the compatibility of both short-run inflection points and linear homogeneity in certain production functions, then the Stonier and Hague [3, p. 226] demonstration of their absolute incompatibility leaves something to be desired. As one who in microeconomics classes agreed with the Stonier-Hague position, citing their geometrical proof in evidence, the embarrassment generates the challenge of detecting where it is these gentlemen went wrong.

Consider their argument: In their Figure 89 [3, p. 226], presented here¹ as Figure 1, linear homogeneity makes $RP = PQ$, and the isoquants vertical displacements of one another. Since the iso-cost curves are parallel, $LP = PM$. Also, since $EP < LP = PM$, $PF > PM > EP$. Q.E.D. "This proof

FIGURE 1

Source; [3, Fig. 89, p. 226].

holds with any equal product map representing a homogeneous production (function) of the first degree. On any such equal product map the marginal physical productivity of a variable factor always falls as more of it is added to a fixed factor" [3, pp. 226-27].

¹ Our Figures 1, 2a, and 2b are taken from Figures 89, 90A, and 90B, page 226, A. W. Stonier and D. C. Hague, *A Textbook of Economic Theory*, 3rd ed. (New York, John Wiley & Sons, 1964), with the permission of the publishers.

They go on to present another case (their Figures 90A and 90B, presented here as Figures 2a and 2b), in which the marginal physical product on

FIGURE 2a

Source: [3, Fig. 90A, p. 226].

one factor may rise before falling, but they make it abundantly clear that this could not represent the short run in a linearly homogeneous production function.

Therefore, the moral of the debate previously cited is, in effect, that Stonier and Hague have committed a Type 2 error in Figure 1, i.e., they accepted the false hypothesis that all linearly homogeneous production functions exhibit universal decreasing marginal products, and made a Type 1 error in Figure 2, i.e., they reject the true hypothesis that decreasing marginal products can be generated by a linearly homogeneous production function. How did this happen?

First, Nutter's production function [1, p. 743]

$$(1) \quad O = 22y^{1/4}x^{3/4} - 20y^{1/3}x^{2/3}$$

FIGURE 2b

Source: [3, Fig. 90B, p. 226].

shows, for y fixed at 1, first rising marginal product of x in the range $0.01 < x < 2.50$ and then falling marginal product in the range $2.50 < x < 100$. Similarly, Rowe's production function [2, p. 746]

$$(2) \quad O = \frac{y^2 x^2}{15y^3 + .5x^3}$$

shows a range of increasing marginal product for x (y fixed at 1) when $0 < x < .5265$.

This indicates that in Figure 1, had more isoquants been drawn, say, for 40 units and 50 units of output, the demonstration of monotonically declining marginal product for x could prove difficult indeed. The persuasiveness of Stonier and Hague's proof seemingly lies in the fortuitous choice of the fixed value for input y . For at ON , point P is located such that it is simultaneously a non-end-point of line segment LF and on the scale line OQ . This means that the crucial theorem of the whole equalling the sum of its parts can be used, i.e., when EP is unambiguously $< LP$ and PM is unambiguously $< PF$, the points are "placed correctly." But, imagine the line segment PF extended to cut a 40-unit isoquant. This would be equivalent to

having originally fixed y at height R . The interior of the line segment R , ... (the intersection with the 20-unit isoquant) is now "badly placed," for there are distances *between* the iso-cost curves and isoquants whose lengths are, in general, geometrically unknowable. This makes the parallel-line theorem used by Stonier and Hague useless for it now cannot be paired with the whole-parts theorem.

An amusing production function nevertheless can be inferred from Figure 1 if we assume that Stonier and Hague's linearly homogeneous function exhibits first diminishing returns then increasing returns to input x . Take the function

$$(3) \quad O(x, y) = y[a + (x/y) + b]^2, \quad (a > 0, b < 0, a + b^2 > 0),$$

and fix y at y^* to get

$$(4) \quad O(x, y^*) = y^*[a + (x/y^* + b)]^2.$$

The marginal product of x will always be positive, i.e.,

$$(5) \quad O'(x) = 3(x/y^* + b)^2 > 0$$

and the marginal product of x will first fall and then rise, for

$$(6) \quad O''(x) = \frac{6}{y^*} (x/y^* + b) \begin{cases} < 0 & \text{if } x < -by^* \\ = 0 & \text{if } x = -by^* \\ > 0 & \text{if } x > -by^*. \end{cases}$$

Thus, if line segment LF were extended far enough, we would see increasing marginal product of input x , a result opposite to that portrayed in micro-economics texts (including Figure 2), and the reverse of the kinds of functions which were the subject of the Nutter-Liebhafsky controversy.

Algebraic specification of production functions, then, seems to be the necessary starting point for any study of "laws" of returns, for Figure 2 could well represent a picture of the Nutter or Rowe functions, a result which the inherent shortcomings of plane geometrical proof convinced Stonier and Hague was "impossible."

Notes on Marxian Economics in the United States: Comment

Martin Bronfenbrenner, in the December 1964 issue of this *Review*, deplored the absence of professors of economics adhering to and teaching according to the viewpoint of Marxism on American campuses. In particular, he expressed the opinion that, given a choice between an off-campus conservative economist like Henry Hazlitt and an off-campus Marxist economist like myself, two-thirds of the present campus economists would choose Perlo as a visiting professor for a year. Bronfenbrenner included a provision that this would be at no cost to the college or university. However, I presume that this provision would not affect the choice of the professors.

To test Bronfenbrenner's observations, in January and February of 1965 I wrote the heads of economics departments of 18 U.S. universities, most of them major institutions, referring to the *AER* communication and indicating my availability as a visiting professor for the 1965-66 academic year. I noted, however, that I would require a normal salary. I included a listing of courses I thought I could teach most effectively and a vita.

Of the 18, 14 replied. Three stated that they or their departments were definitely interested and would investigate to find out what could be done. By now it is evident that none of these three will offer me a visiting professorship for the 1965-66 academic year. However, from further correspondence and conversations I conclude that the subject is still alive in all three, either for a semester during the academic year, for the succeeding summer session, or for the following academic year.

From correspondence and conversations with two of the departments concerned, it appears that administrative authorities (Board of Trustees, Dean of Faculty) may well prove decisive obstacles, although they have not yet been tested.

Ten heads of departments stated that there were no appropriate openings for the 1965-66 academic year, either because of lack of funds or because all suitable positions were already filled, or both. Of these, four stated that they liked the idea and would attempt to carry it out for a later academic year. A fifth stated agreement with Bronfenbrenner but made no mention of the future. He expressed hope that some other university would be able to arrange a visiting professorship for me, as did several others. The remaining five in this general category made no mention of later years.

The final respondent was "intrigued" by my suggestion and said he would give it thought. While preferring me to Hazlitt, he was wary of "doctrinaire Marxists."

One respondent in writing, and a number of professors in conversation, noted that state universities "have more problems in employing an avowed Marxist" than privately endowed institutions because Trustees must consider possible legislative repercussions as well as their own inclinations.

Most responses were friendly in tone, although some were merely courteous, and some were enthusiastic.

Concerning the four heads of departments who did not reply, I do not assume that this designates hostility or indifference. I identified heads of departments from the *1964 Handbook of the AEA*. In a number of cases the head of department had changed by this year, as I discovered when my letters were

answered by different persons, sometimes after several months delay. It is possible that similar accidents accounted for some or all of the four unanswered letters.

* * *

On another subject: this *Review* has accepted and published the two contributions I offered, and it has a reasonably good record of reviewing my books and, I believe, books of other Marxists. But no Marxist has appeared on an annual meeting program of the American Economic Association since Paul Baran was a discussant in December 1959. I, for one, have never been invited to participate in an AEA program, although I have been in those of some other professional associations.

It seems to me that Marxist views should be solicited for all annual meetings of the American Economic Association. At least five of the major subjects of the 1964 annual meeting really required presentation of a Marxist viewpoint to give a rounded picture of economic thought and research results:

1. Economic Growth: International Comparisons;
2. Comparative Economic Systems: Nationalized Industry;
3. Economic History: Its Contribution to Economic Education, Research, and Policy;
4. The New National Econometric Model: Its Application;
5. The Economics of Poverty.

This is not to decry the many good papers that were presented, nor to assert that it would be easy to find in the United States Marxist economists available to present papers on all of these subjects. I assume that program invitations are decentralized, with a given professor in charge of each subject. Thus a certain amount of advance coordinating may be necessary to insure the invitation of Marxists to participate in the programs. But I daresay such difficulties could be overcome and the Association could markedly improve over its past record in this respect.

The Burden of the Debt: A Mathematical Proof

A familiar proposition is that we owe the national debt to ourselves. However, this proposition has still not been rigorously proved. My intention is to provide such a proof.

The proposition that the national debt as a liability must just equal the total of the associated assets can be stated as follows:

$$(1) \quad \sum IOU's = \sum UOMe's.$$

If we divide both sides of the equation by OU , we have:

$$(2) \quad \sum P's = \sum Me's.$$

BOOK REVIEWS

General Economics; Methodology

On Economic Knowledge—Toward a Science of Political Economics. By ADOLPH LOWE. New York and Evanston: Harper & Row, 1965. Pp. xxi, 329. \$6.95.

This volume presents Adolph Lowe's distillation of "forty years of reflections about the subject matter and the method of a science of Economics." He explains that "the reconstruction of economic science is the ultimate aim of this inquiry" (p. 159). Lowe's reconstruction includes not only (1) a broadening of the scope of economics, but also (2) the construction of a theory of controlled economic systems, and (3) the application of new methodological procedures.

With regard to the nature and scope of economics it is Lowe's position that, while the body of universal or general economic theory developed by economists from Smith to Keynes is very useful and cannot be dispensed with, nevertheless this general theory is incomplete since it has little connection with the sociopolitical environment in which the market system is lodged. Lowe asserts that economics should be extended beyond the body of "traditional" economics to include an analysis of the factors and forces in the institutional environment that have a large impact on the operations of the market system. He combines the study of "man-to-matter" relationships (nonsocial) in the area of pure economics with the study of "man-to-man" relationships (social) in the sociopolitical environment of the private market system in order to create a Political Economics. This economics "tries to relate the economic core process [the market system] to the dominant factors of the sociopolitical environment" which have much to do with determining the structure and functioning of the market system (p. 249). Political Economics then becomes the study of "controlled economic systems."

The controlled economic system that is Lowe's primary concern is the "organized capitalism" of Western Europe and the United States. In organized capitalism, market behavior has been greatly altered as the result of the increasing immobility of industrial capital, the growing uncertainty of business expectations, and the very long-term financial commitments required of corporate enterprises. In this new era of capitalist development the public authorities endeavor to provide a better working of the private market system with the aid of manipulative and command controls. The public control of market activity is designed to reduce economic uncertainty and to provide an economic climate favorable to the good functioning of private enterprise. Lowe sees Western economic systems moving toward some kind of capitalist planning, such as is found today in France, in which decentralized private economic de-

cision-making is combined with manipulative controls and a minimum of "command" control.

Having broadened the scope of economics to include the analysis of the institutional environment of the market system, Lowe then raises the question as to whether or not his Political Economics, like pure economics, is a science that ascertains "empirically relevant theorems" or "repeatable patterns" of behavioral interdependence. He explains that the studies of the sociopolitical process made by Karl Marx and other investigators of capitalism have not revealed any "regularities of motion sufficiently strict to be formulated in laws of coexistence and succession." Lowe proposes to remedy this deficiency of broad-gauged economic analysis by using a new methodological approach in which observation and analysis are combined with "participation" or "actual intervention in the course of events."

Lowe's new methodological procedure, described as "instrumental inference," reverses the traditional procedure in which the economist moves from a postulated initial state in which known behavior and motivations lead to a terminal state of market equilibrium. Lowe explains that in organized capitalism the government sets up certain macro-goals relating to such matters as economic growth and consumption and investment levels. Once these goals have been established, it is then possible to infer or demonstrate what economic arrangements and business behavior are necessary to assure goal attainment. The postulated terminal state at the end of the control or plan period indicates what economic policies must be adopted in the initial state (at the beginning of the control or plan period) in order to achieve the projected national economic goals. According to Lowe's interpretation, public control bestows on the economic processes of the real world that degree of orderliness that is a precondition for theoretical generalization. It is then possible to ascertain empirically relevant theorems and to predict the course of economic behavior towards goal attainment. The motion of the whole economic system becomes determinate and one can then speak of a science of Political Economics.

Lowe's views on the nature, scope, and methodology of economics are not likely to find much acceptance among a large section of the economics profession. Many economists will not accept his interpretation of the evolution of the capitalist system towards a controlled economic system. Others are not likely to follow his suggestion that they should move beyond the limited confines of general or pure economic theory to take account of the impact of factors in the sociopolitical environment on the operations of the market system. Lowe's reflections on economics should have a special appeal to economists like Gerhard Colm, Clarence Ayres, Gunnar Myrdal, and others who have already been working along the lines suggested by him. These heterodox economists will in general find themselves in agreement with Lowe's views on the nature, scope, and methodology of economics. More than this, Lowe's reflections on economics should provide a much-needed scientific underpinning for the work of economists who do not fit into either the "free enterprise" or the Keynesian mold.

University of Maryland

ALLAN G. GRUCHY

Patterns of Market Behavior. Edited by MICHAEL J. BRENNAN. Providence: Brown University Press, 1965. Pp. vii, 258. \$8.50.

The collection of thirteen excellent essays in *Patterns of Market Behavior* is published as a tribute to Philip Taft on the occasion of his sixty-third birthday. The essayists are present and former colleagues, and former students. The general high quality of the essays in the volume allows one to conclude that Professor Taft's associates have delivered their tribute to him in commendable fashion.

Although Taft's primary interests and contributions are in the field of labor economics, each contributor to the volume has developed an essay in a subject area of his own interest and speciality. In keeping with the present state of methodology in economics, seven of the essays are cast in highly mathematical terms. To these the reader must bring some degree of sophistication in mathematics to gain a full understanding of the author's thesis and objectives.

The editor has arranged the essays in the volume under four major market categories: Commodity Markets: "On the Determination of Prices in Futures Markets," "Optimal Programs for Sequential Investments," "Some Economic Aspects of Outdoor Recreations"; Resource Markets: "A More General Theory of Resource Migration," "Improved Allocation of Labor as a Source of Higher European Growth Rates," "Time, Work, and Welfare," "Changes in Occupational Structure"; Money Markets: "A Commentary on Some Current Issues in the Theory of Monetary Policy," "The Bills Only Doctrine in Retrospect," "The Integration of Simple Growth and Cycle Models"; International Markets: "The Effects of Devaluation in a Growing Economy," "Differential Growth Rates Among Open Economies: Theory and Fact," "Economic Development and Comparative Advantage." A complete bibliography of Taft's writings is also included.

Some flavor of the substance of the essays can be gained from a brief review of several of them. James N. Morgan's article, "Time, Work, and Welfare," is especially timely in view of the current emphasis on the poverty problem. He uses original empirical data to examine the factors conditioning the annual hours of work an individual is willing to offer; other data shed light on the factors coincident with wives in the labor force; he develops an excellent exposition on the socioeconomic factors which accompany poverty in the United States.

Mark B. Schupack, in his essay, proposes a workable means of measuring changes in the age-structure of different occupations. Hyman P. Minsky in "The Integration of Simple Growth and Cycle Models" develops a framework within which to analyze growth and cyclical forces in an intermediate time-horizon of from ten to fifteen years. Minsky incorporates both aggregate supply and demand factors into his model, suggesting that the traditional short-run and long-run models have been concerned with only one or the other of these variables. His thesis should evoke some interesting discussions. Finally, by way of illustrating the scope of coverage, Jerome L. Stein takes Myrdal's thesis that the free play of market forces aggravates interregional inequalities in income per capita and demonstrates that the thesis is not tenable in a free capital movement area such as the United States. This article is wor-

thy of study by theorists of regional economic development. Because of the diversity of subject matter covered, and in view of the good quality of the material, we recommend that the profession become acquainted with this excellent volume.

GERHARD N. ROSTVOLD

Pomona College

The Economics of Competitive Coexistence—Convergence Through Growth.

By CYRIL A. ZEBOT. New York: Frederick A. Praeger, 1964. Pp. ix, 262. \$6.50.

This at times lucid and broad-gauged essay attempts an ambitious analysis of growth prospects of the three great divisions of the sociopolitical world: the Western, the Eastern, and the Developing Peoples. Communist strategy centers on overtaking the West by a resolute growth effort (pp. 3f.). The richer Western peoples also need further growth to satisfy their developing needs for a more comfortable and fuller life (p. 56). These needs are not checked by a Galbraithian tendency toward diminishing marginal utility of income growth nor are they produced by an emulative drive or by advertising effort (pp. 51, 57).

The developing societies can only realize their growth aspirations by educational programs which foster cultural skills and aptitudes required for industrialization. This human development allegedly overshadows in importance the coercive role of the state (pp. 18f.) which can, however, play a constructive role in providing education and in arranging for international or regional economic cooperation (pp. 21f.) including formal aid programs of advanced Western countries (p. 22).

The root problem of all three peoples—Western, Eastern, and Developing—is inflation. In the West the drive to inflation springs from the pressure of unmet wants for higher living standards noted above, by an institutionalized form of unionism which aggressively pushes up money wage levels (pp. 86f.), and by business power to administer prices according to standards which avoids downward price adjustments when unit costs fall and which otherwise strives for stable profit margins and maximization of sales rather than profits (p. 94). The drive to raise wage rates faster than productivity stimulates automation which thus represents “a very intensive substitution of mechanization for labor” (p. 88). This generates unemployment, on the one hand, and excess credit expansion on the other to finance the larger volume of output produced with augmented payroll charges and sold at somewhat higher price levels.

Communist and underdeveloped economies also experience the drive to inflation but in other forms. In underdeveloped countries it arises out of a tendency to introduce an advanced industrial technology ahead of the corresponding growth of technical skills, thus producing unemployment, high production costs, and inflation (p. 123). In the Soviet Union inflation arises out of the totalitarian character of the communist political economy and its ruling class. This political economy centers on manipulation of physical controls

with a corresponding neglect of the market-clearing and allocative functions of prices which fail to correspond to costs in any uniform way (pp. 125-27). Shortages and planning deficiencies are borne by the consumer who suffers from a chronic shortage of goods which undermines efforts at economic management or service of the people in their daily lives. In the Soviet economy inflationary pressures are thus directly related to the "gap that separates the totalitarian dictatorship of the Soviet government from the supposed socialist character of the Soviet economy" (p. 129).

The remedies for inflation, though taking different forms in Western, Eastern, or developing societies, works out to a "grand convergence through growth" (the subtitle of the book and the theme of the final chapter, "Conflict or Convergence"). In the Western world these remedies must involve regulation through fiscal policy and tax reductions of aggregate demand, "geared to a realistic level of full employment," and supported by credit policy which plays an adaptive, not an initiatory, role (pp. 96-107). Organized labor must agree to limit wage increases to productivity increases supplemented by premium payments in areas of labor shortage. Industrial management must permit final product prices to fall as well as rise. Procedurally, wage negotiations between management and labor need to be facilitated only by institution of a public chairman who will preside over the negotiations (p. 110).

The Eastern world is advised to meet the inflation problem by leavening the communist economy with socialist principles of politics. These would widen the role of the consumer interest and give increased emphasis to the price system, thus leading to a wide-ranging decentralization of "authority and institutions" (pp. 139-42). The underdeveloped societies will doubtless develop a political economy with a huge public sector, but which in most essential respects would fit into the decentralized, market-oriented political economy of the West.

This is merely the bare frame of argument which is expounded in appendices half again as large as the book. Inevitably so wide-ranging an argument is vulnerable. Only in this decade could the basic problems of so many peoples be reduced to that of inflation, which thus takes on the role of a universal sin. Did not Keynes but yesterday expound on the value of inflation as stimulating enterprise and loosening the hold of the dead hand of the past? Did not Schumpeter ascribe all development to innovation financed in a burst of inflation? Did not Wesley Clair Mitchell show us clearly why cyclical expansions would generate price rises?

And even if inflation is totally evil and sinful, still it hardly ranks as the predominant problem of our times. The Communist world desperately needs constitutionalism or limited government under law which is more difficult to achieve than a price system toward which clever Eastern technocrats aspire or devices of inflation control which Communist bosses can devise. I find myself resenting the notion that all underdeveloped peoples have the same root problems. Some may need family planning devices. Others may need to overthrow parasitic landed aristocracies. Other societies may need to disestablish a standing army and conquer militarism or to develop an orderly form of democratic government.

In the Western world too, problems are more varied than Cyril Zebot indicates. At least we in the United States are plagued with evils more deadly than creeping inflation: our inability to revamp the inherited chaos of municipal government which is turning our great metropolitan communities into shambles; the emergence of the handout as the supreme political principle of a welfare state and the ordering device for the distribution of a rising share of our national income; the domination of our public life by the public relations manipulators and bureaucracies of the mass media. And I don't like to see credit policy assigned merely an adaptive role.

MANUEL GOTTLIEB

University of Wisconsin-Milwaukee

Our Depleted Society. By SEYMOUR MELMAN. New York: Holt, Rinehart and Winston, Inc., 1965. Pp. x, 366. \$4.95.

This book is an analysis of the economic consequences of the large-scale diversion of resources to military purposes. The author, a professor of industrial engineering at Columbia University, attempts to demonstrate that the nation's capacity for generating economic growth has seriously declined as a result of the high level of defense preparation.

In the 15 chapters of the book, the reasoning underlying the author's conclusion appears to consist of three propositions:

1. U.S. national defense policy has relied largely upon a concept of deterrence—the prospective losses with which the U.S. military forces confront an opponent have been structured so as to far exceed whatever gains the opponent may foresee; hence, the present amount of deterrence is either excessive or self-defeating.
2. National defense has absorbed scarce resources from their peacetime employment.
3. Defense preparations use a very large quantity of a comparatively small and fixed supply of technically skilled personnel.

To what extent can the methods of economic analysis be used to substantiate the three propositions? Taking the first proposition, the author advances two types of proof. The first is the over-kill line of reasoning: we possess sufficient redundancy of nuclear weaponry and their delivery systems to accomplish many times over any conceivable set of missions. The second type of substantiation, which is meant to explain why over-kill exists, consists of invoking the old merchants-of-death argument—the conspiracy of the military-industrial complex. A proof of a poorly performing military-industrial complex requires more than an invocation of former President Eisenhower's good name, which is the only evidence offered. One has a right to expect some discussion of the distinctive attributes of the defense industry's structure which might produce such an outcome. Unfortunately, the administrative pricing system which conditions industrial contractors' behavior has not been analyzed. Similarly, the intra-military reward-disbursement-behavior relationship is another empty analytical box. But it is simply not legitimate to assume the

worst possible case without any qualification or caution offered to the reader.

The second proposition requires the reader to believe that, if defense expenditures were substantially reduced, a large number of unsatisfied demands could be met, such as education, housing, and health care. No mention is made that these demands might remain unfulfilled even if there were no defense expenditures. The concepts of effective demand or the older distinction between needs and wants would have been appropriate in the context. Either one would have served to qualify what can only be called very excessive oversimplification.

The third proposition is in a sense a restriction on the previous one. It is argued that certain kinds of skills, especially those of engineers and scientists, are used in the production of defense preparedness in excessively large amounts. Thus, the author imputes the supposed technological retardation of the railroad industry to short supply of system engineering design talent. But the technological status of the railroad industry can be explained readily in terms of the economics of automobile and truck transportation and a distinctive administrative pricing system imposed upon railroads that insists upon a physical maximization of tons per train mile. In order to maintain that an absolute shortage of engineers and scientists exists, it is necessary to argue that the available supply of suitably endowed individuals is fixed. But the distribution of capabilities and capacity for learning in the population is usually shown to be quite widespread. Determination of the specific industries and occupations that suffer the greatest diminution of labor supply as a result of increased defense efforts must be assessed after the entire redistribution of labor occurs. It is very doubtful that the availability of skilled individuals for peacetime occupations has declined by the number who have shifted to defense employment.

General Electric-TEMPO, Santa Barbara, California

**Price and Allocation Theory; Income and Employment Theory;
Related Empirical Studies; History of Economic Thought**

Probability and Profit: A Study of Economic Behavior Along Bayesian Lines.
By WILLIAM FELLNER. Homewood, Ill.: Richard D. Irwin, Inc., 1965.
Pp. x, 239. \$7.50.

"A good many reasonable decision-makers—though by no means all—seem to act differently depending on whether they act under the influence of shaky degrees of belief, i.e., of probabilities the numerical values of which are highly unstable in their minds, or act under the guidance of firm and stable degrees of belief." Thus on page 4 William Fellner asserts the empirical relevance of the theory that forms the cornerstone of this monograph.

Fellner's primary objective is to broaden the scope of the Bayesian approach to decision-making under uncertainty. First, he rejects the limitations imposed by the strict frequentist approach (represented by Richard von

Mises), according to which probability reasoning applies only to the limited class of decisions involving events with objective probabilities. Second, he rejects the pure subjective probability approach (represented by L. J. Savage), according to which strict probability reasoning can handle a very wide range of decisions where probabilities are represented by degrees of belief. In place of these extreme positions, Fellner offers his own "semiprobabilistic" approach, according to which decision-makers *may* slant (usually downward) probabilities pertaining to events not encompassed by the frequentist approach. These probabilities may require special treatment either because they are interpersonally controversial or are unstable in the mind of the decision-maker, or both.

Thus, for example, we might observe that a person will bet on either heads or tails on the flip of a fair coin at a 2.1 to 1 pay-off ratio, but will not bet on *either* the proposition that the United States will put a man on the moon by the end of 1970 *or* the proposition that the United States will not put a man on the moon by the end of 1970, at the same payoff ratio. According to the subjectivists, the propositions about the coin toss and those about the moon landing all fall into the same general class. This implies that a rational person who is willing to bet on the coin toss at a 2.1 to 1 pay-off ratio must also be willing to bet on at least *one* of the propositions about the moon landing at the same ratio, since at least one of the propositions must have a subjective probability of .5 or more. According to the frequentists, the propositions about a moon landing are not comparable to the propositions about the coin toss and cannot be explained on the same or similar bases.

Fellner would contend that degrees of belief about the moon landing are likely to be shaky, and may therefore be slanted or discounted. For propositions about which degrees of belief are shaky, the decision-maker's decision weights, which are slanted probabilities, need not sum to one for all possible mutually exclusive events. Thus, a rational investor may refuse to accept either bet about the moon landing even though he will bet on the coin toss. In most other respects, however, the treatment of slanted probabilities parallels the procedures applicable to strict probability reasoning. Consistency requirements for semiprobabilistic behavior are set forth by the author, and the relation of these to the requirements of strict probability theory is discussed.

Fellner outlines a theory of profit that encompasses the semiprobabilistic behavior he envisages. He first describes a purely probabilistic model, in which the investor carries his commitment up to the point where the expected marginal utility of potential gains is equal to the expected marginal utility of potential losses—that is, where expected total utility is maximized. Fellner then incorporates semiprobabilistic behavior into the profit model. The revised model can explain behavior that cannot be *interpreted* by a pure probability approach. Fellner argues, furthermore, that his version is superior to such rule-of-thumb approaches as maximin of gain, maximax of gain, and minimax of regret.

Of greatest interest to those who wish to assess the usefulness of Fellner's contribution for economic analysis is Chapter 7. Here the author presents illustrations of his own approach, applying it to three problems in economic

theory. In the first illustration, it is shown that profit maximization leads the semiprobabilistic (slanting) investor to undertake a lower level of investment and output than purely probabilistic considerations would dictate. Fellner indicates that his approach may be used to rationalize observable tendencies toward average cost pricing.

The second example is related to "Cournotesque" behavior. Fellner shows how the introduction of uncertainty may explain why oligopolists pursue strategies that, compared with the ideal strategy of joint maximization, work to their mutual disadvantage. However it appears that Fellner's conclusion depends only on the introduction of uncertainty into the model and has no necessary connection with semiprobabilistic behavior.

The third illustration concerns investor preferences for liquid assets. James Tobin's model, which explains liquidity preference as behavior towards risk, is presented in slightly modified form, so as to take semiprobabilistic behavior into account. Downward-slanting individuals will play it safer (hold more cash, less securities) than pure probability reasoning would suggest. However—and this Fellner considers more important—the Tobin model assumes that the time of liquidation of noncash assets is known with certainty. But, asks Fellner,

... what if . . . we take account of the fact that the individual assigns various probabilities to the prospect that he may have to sell at various dates, and to the prospect that he may be able to wait for a convenient date of liquidation without a sacrifice of other important objectives? In such a modified model a downward-slanting tendency expresses itself *also* in an inclination to overweight the probability that the security *will have to be sold at a time when its price is low*. I believe that, in the real world, this may well be the most important manifestation of the downward-slanting tendency.

The observable conservatism of financial managers *can* be explained, however, on strict probability grounds. Reduction of cash holdings increases the probability of having to liquidate on unfavorable terms; as a result, the marginal contribution of cash to the expected value of a portfolio increases as less cash is held.

Thus it would seem that, among the three illustrations provided by Fellner, the first argues most strongly for injecting semiprobabilistic behavior into the model. Nonetheless, the "slanting" notion has great intuitive appeal, especially as it applies to decisions of managers who must account to others, such as boards of directors, for decisions based on shaky judgments.

In addition to Fellner's own theory, the book contains discussions of the historical development of the theory of decision-making under uncertainty, and a valuable bibliography of 52 items with extensive commentaries. An appendix presents some not-very-compelling results of betting experiments with Yale students. *Probability and Profit* should interest all economists concerned with decision theory and should be a useful addition to reading lists of courses dealing with this subject.

SAMUEL B. CHASE, JR.

The Brookings Institution

Microstatics. By WILLIAM S. VICKREY. New York and Burlingame: Harcourt, Brace and World, Inc., 1964. Pp. x, 406. \$7.95.

Metastatics and Macroeconomics. By WILLIAM S. VICKREY. New York and Burlingame: Harcourt, Brace and World, Inc., 1964. Pp. x, 314. \$7.50.

We have here, apparently, Professor Vickrey's course in economic theory, as conveyed to us in a highly evolved set of lecture notes. All in all, it is an excellent course. It has its ups and downs, however, and more so than most courses. Both great triumphs and virtual disasters of pedagogy may be found in these two volumes. The proportion of triumphs is a good deal higher in the micro volume, where the author's heart presumably lies.

The unevenness in quality is related to a rather remarkable variability in the level and analytical style of the discussion. From page to page, Vickrey alternates among the roles of rigorous theorist, casual empiricist, philosopher of science, summarizer of uncited empirical investigations, critic of economic policy, worker of complicated numerical examples, popularizer of mathematical economics, and others as well. At one point, the reader will be led by the hand at a pace appropriate to an intermediate theory course, then there will be a section that will provide a good review for a doctoral candidate studying for his comprehensives, then a particularly novel perspective or insight likely to be helpful to the author's academic colleagues, then an example of extraordinary precision with theoretical fine points, and finally, there are sections which seem to be hasty summaries of analyses that Vickrey has done on the back of an envelope somewhere. The general effect is fairly lively and interesting. One great virtue is that the real world does not get hidden behind the analytical apparatus for very long periods at a time. On the other hand, the transitions in level and mode can be disconcertingly abrupt. The reader may get confused as to whether the world under discussion at a given point is the real world or some abstract theoretical world, and if the latter, whether the assumptions characterizing this world have been fully spelled out. Also, the instructor who uses these volumes as textbooks will have to do some careful planning if he is to provide the variations where Vickrey supplies only the themes, and the themes where Vickrey supplies only the variations. The latter situation occurs more frequently than most instructors would probably desire.

The first chapter of the micro book is, inevitably, the "What Is Economics?—What Is Economic Theory?" chapter, and it is a model of its kind, both sophisticated and concise. The next three chapters provide the analytical core of microeconomics, under the headings consumption, competitive exchange, and production. On the whole, these chapters are excellent. They are the best in the two books from the point of view of careful and insightful presentation of basic theoretical material; given the decision to eschew calculus or more powerful techniques, it would be difficult to surpass the precision and clarity of Vickrey's development of most of the central propositions.

Still, one can quibble here and there. For example, considering the general level of precision in these chapters, one might expect something better by way of introduction to the utility concept than the following: "Whether the economic unit is a single individual or a more or less cohesive group, our econom-

ic theory will assume for the time being at least that there is some valid and worthwhile objective which the behavior of the unit is intended to secure and in terms of which this behavior can be rationalized. . . . We will call the degree to which a unit achieves its objectives the satisfaction or 'utility' of this unit" (pp. 20-21). The ensuing discussion provides only a hint of the line of development in which the utility function appears as an implication of more fundamental assumptions about rational behavior, and it completely obscures the distinction between the use of rationality assumptions as an approach to positive economics and the combination of rationality assumptions and individualistic value judgments that lies behind welfare economics.

Also, both the consumption and production chapters suffer from the absence of any explicit use of the concept of a function. This concept is enormously easier to understand than some of the more arcane and arachnoid diagrams on which this "elementary" exposition of microeconomics is based. And in Chapter 6, Vickrey has an extensive discussion of a "social-welfare function of the individual rank orders"; as functions go, this is not an easy one to understand. Nevertheless, the treatments of many goods and many factors of production never refer to demand functions and cost functions, and thus they leave the uninitiated reader with very little information about the n -variable generalizations of the diagrammatic analyses. One does not need to use calculus to make the point that the general outcome of an optimization process can be summarized by the functional dependence of certain quantities on certain other quantities.

Chapter 5, entitled "The General Competitive Equilibrium," deals in a perfunctory and inexact manner with the optimality properties of competitive equilibrium. There is a sketchy argument that would not convince a skeptical reader that competitive equilibrium is Pareto optimal, followed by a section entitled "The Assumptions of the Theorem that Competition Is Optimal." In this discussion there is a complete muddling of conditions that are defining of competitive equilibrium, conditions that are necessary for its existence, conditions that are necessary for its Pareto optimality, and conditions that are necessary if every Pareto-optimal position is to be achievable as a competitive equilibrium. In direct violation of the intentions expressed in the preface and the viewpoint put forward in the introduction, the distinction between theoretical validity on given assumptions and empirical relevance is abandoned. Actually, almost three-fourths of this "general equilibrium" chapter is given over to variations on the theme of determining optimal resource allocation by maximizing the net social "surplus," measured by the appropriate areas on a demand and supply curve diagram. Some of this is very instructive and some of it is very tedious; the necessary caveats for the whole business are somewhat underemphasized.

The next chapter deals briefly with compensation criteria and their problems, but is devoted mainly to a very nice summary exposition of the Arrow impossibility theorem, single peakedness, and so forth. As suggested above, the implicit assumption about the reader's ability to pick up abstract concepts is drastically different here from what it is in the earlier chapters. The same

comment applies to the exposition of game theory in Chapter 9. The seventh and eighth chapters contain a workmanlike development of familiar results on monopoly, oligopoly, and monopolistic competition, distinguished by a good deal of attention to product differentiation and spatial competition.

The term "metastatics" in the title of the second volume refers to intertemporal analysis in the absence of uncertainty. Under this general heading Vickrey presents the elements of capital theory and Fisherian analysis, and discusses the classification of inventions, anticipated seasonal fluctuations when storage is possible, acceleration effects, and von Neumann-Morgenstern utility theory. Some of these topics are treated with less thoroughness and less emphasis on analytical methods than their importance would seem to justify, but the discussion is free of theoretical error and confusion, and has only minor faults of exposition.

Chapter 5 is a good introduction to money, the demand for money, and the behavior of banks. The following chapter, in "Macroeconomic Variables and Concepts," is not at all satisfactory as an *introduction* to this subject. The emphasis on the conceptual difficulties involved and the arbitrary nature of many of the definitions in any practicable system of national income accounts is overwhelming, and the reader does not learn how these problems have been handled in the Department of Commerce or any other system of accounts.

Chapter 7 covers the traditional topics of macroeconomic statics. The discussion begins with classical views on the mechanisms that should produce full employment, proceeds from a critique of these views to the development of a Keynesian model, and finally to an integrated model that may be rendered as $S(i, y) = I(i, y)$ and $L(i) \cdot y = M$. The latter is presented diagrammatically and briefly put through its paces with schedule shifts and monetary and fiscal policy. The particular form chosen for the demand for money relation gives the integrated model a more classical flavor than when transactions and speculative demands are treated as additive, but the substantive difference is small. There is the barest mention of real balance effects. In contrast to most of the material in these volumes, this chapter is neither particularly good nor particularly bad.

The last three chapters of the second volume are grouped together under the heading "The Dynamics of Changing Expectations." Topics covered include cobweb phenomena, Hicksian trade cycles, the elasticity of expectations, Harrod-Domar growth theory, and the problems of accurate public forecasting and open public policy. Particularly noteworthy are the attention given to a fairly elaborate Hicksian cycle model (with specific quantitative relations supplied and worked out for 131 periods), the interesting discussion of the problem of open public policy, and the utter absence of any reference to neoclassical growth theory *à la* Solow, Swan, Tobin, *et al.*

Five chapters of the micro volume have mathematical appendices. These do not attempt a complete development of the main elements of price and allocation theory, and are probably somewhat too concise to be of much value to the individual encountering this sort of material for the first time. In the appendix to the third chapter the utility maximization problem of the consumer is incorrectly formulated as a maximization problem both in quantities consumed and

in the multiplier associated with the budget constraint. This will not do, especially since the budget constraint is treated as an inequality and the possibility of satiation admitted. In the correct formulation, the Lagrangean expression is *minimized* with respect to the multiplier.

Several of the chapters in both volumes have exercises appended for the reader. These appear likely to yield large gross returns, but the return over cost will probably appear small to the students. It is interesting that no exercises are included that involve manipulation of a statical macroeconomic model, but exercises *are* provided in which the student is expected to carry through the numerical calculations for the elaborate Hicksian cycle model! Both volumes have indexes in which errors of omission have been effectively minimized. (Sample selection from the macro volume: "Brick, as money base," "Brouwer's fixed-point theorem," "Rabbits in Australia," "Shoplifting in the national income.") There is a lengthy list of readings and references, arranged by topics within chapters, at the end of each volume. The arrangement by topics is not an adequate compensation for the absence of footnotes in the text proper; there are a great many points at which the reader deserves more direct guidance to alternative or supplementary discussions. Apart from sections that treat numerical examples or explain complicated diagrams, the writing is fluid and enjoyable to read.

It is a rare course in economic theory that cannot be improved by incorporating portions of these books on the reading list. They are highly recommended for highly selective use.

SIDNEY G. WINTER, JR.

University of California, Berkeley

The Sources of Increased Efficiency—A Study of DuPont Rayon Plants. By SAMUEL HOLLANDER. Cambridge: M. I. T. Press, 1965. Pp. xii, 228. \$10.00.

This book is concerned with technical change: what it is, how it comes about, what its characteristics are, and how important it is. In the first chapter, Professor Hollander reviews the literature that treats technical change as a shift in the aggregate production function, and notes some of the shortcomings of this approach. He agrees with Domar that this concept of technical change is a catchall, or residual. The remainder of the book consists of a detailed examination of this residual in a single industry: rayon manufacture.

Technical change is defined as "the introduction or the spread of cost-reducing changes in technique" (p. 4). The author then asks, "To what extent can changes in the productivity of the firm's inputs be ascribed to 'technical change' in the narrow sense?" (p. 21). As the problem is defined, changes in input productivity must be due to technical change, economies of scale, or changes in the quality of inputs. As the author gives little attention to input quality, much of the book is concerned with apportioning increases in productivity between technical change and economies of scale.

Hollander does not use the usual reversibility criterion for distinguishing between the two. Rather, he confines economies of scale to a plant-expansion effect: the spreading of overhead costs over a larger level of output. The use

of more efficient methods of production at larger levels of output is regarded as technical change, although most economists would term this economies of scale. On this basis, Hollander finds that technical change explained between 35 and 100 per cent of the reductions in unit cost in the plants in his sample.

Technical change is subdivided into indirect (innovations intended to increase volume) and direct (innovations designed to lower the cost of producing a given volume). His results show indirect technical change to be more important than direct. This probably reflects the fact that output was expanding rapidly in the period under consideration. It is difficult to see what other significance attaches to this finding.

A further distinction is made between major and minor changes in technology. A major change is one considered "difficult" prior to its introduction. On this basis, minor changes were found to predominate. But the reader is not told why major technical changes that have little effect on unit costs are introduced, despite their difficulty. Why isn't R and D effort channeled into the development of further minor changes in technology, some of which have an appreciable effect on cost? The author provides a partial answer by explaining that the rate of introduction of major innovations limits the rate of minor technical change. But in this case, of what interest is the distinction?

Hollander examines also the relative importance of embodied and disembodied technical change, and finds that 80-90 per cent of technical change was embodied. He argues also that replacement investment was more important than expansionary investment in leading to improvements in technology. This might suggest that plant managers are more likely to introduce new techniques when they are replacing obsolescent equipment than when they are adding to their capital stock. Alternatively, however, the result could simply mean that the timing of replacement investment is related to the availability of new technologies. In the latter case, the author's distinction has little meaning. Moreover, even if the former interpretation is correct, then the observed importance of replacement investment is no doubt simply a reflection of the importance of output-increasing technical change.

Finally, the author considers the sources of innovation, and finds that minor innovations tended to be developed internally, whereas major innovations tended to be developed in the research laboratory. One wonders whether this last point might in part reflect circular reasoning, considering the way in which major and minor innovations are defined. Is it not more likely that an innovation arising out of the work of a formal research unit would be regarded as "difficult" while an innovation developed on the spot would be regarded as "easy"?

This book is important as a case study of technical change at the micro level. However, it is a bit heavy on detail. Two-thirds of the book consists of a blow-by-blow account of changes in technology over time in each of five plants; one wishes that this material were presented in summary form. At the same time, the study could usefully have included a great deal more economic analysis, as well as further discussion of the policy implications of the author's findings.

A History of Marginal Utility Theory. By E. KAUDER. Princeton: Princeton University Press, 1965. Pp. xxii, 247. \$6.50.

This is a strange book. For one thing, it merely sketches the early history of utility theory and gives a somewhat disjointed account of recent developments, concentrating almost exclusively on the Austrian marginalists in the conviction that "the members of the Viennese group have probed deeper into the value problem than other economists." For another thing, while dealing solely with the logic and structure of marginal utility theory, it is full of expressions of alarm about the decline of marginal utility doctrine in our own times, insisting that "the neglect of marginal utility would deprive the theorist of an essential tool needed for economic analysis." And yet the entire argument of the book is conducted without any reference to the actual economic content of marginal utility theory: "the price theory based on marginalism has been intentionally neglected." The author claims that "the essential achievements" of the theory are "a thorough analysis of consumer behavior and some valuable insights into the demand-structure." But this claim is hardly substantiated by his account of the interminable Austrian discussions over the fine points of household planning. In the final paragraph of his book, the author concedes in a magnificent understatement that "during the whole history of marginal utility, the theorists have not always checked their findings against observed cases and statistical evidence. In natural science every discovery is tested. Why have we done so little?" If this rhetorical question had appeared at the beginning of the study, instead of at the end, a different and, I cannot help feeling, a more useful history would have emerged.

Marginal utility theory up to the introduction of the problem of choice under uncertainty by von Neumann and Morgenstern was fundamentally concerned with the rationale for downward-sloping demand curves, and it cannot be understood except in relation to the demand behavior that it attempted to explain. All along there were theorists, such as Cournot and Cassel, who employed demand functions without worrying about a utility substructure. Most economists rejected this positivist approach that seemed tantamount to throwing away information derivable from introspection. Since demand curves cannot be simply observed, it was hoped that the specification of behavioral assumption—and that is all that utility theory is—would add information on the nature of demand functions. And yet the long and tortuous history of utility theory presents a disheartening picture. Few of the sponsors of utility theory were interested in testing the behavioral implications of the theory and, indeed, on the whole utility theory was not a fruitful source of hypotheses about demand. The work before us confirms Stigler's conclusion in his brilliant paper "The Development of Utility Theory" (*Journal of Political Economy*, August and October 1950) that the practical upshot of fifty years of utility theorizing was nothing more than the proposition that "if consumers do not buy less of a commodity when their incomes rise, they will surely buy less when the price of the commodity rises."

The book opens with a chapter on the delayed acceptance of marginal utility theory in the eighteenth and nineteenth century, developing the thesis that Catholic-Thomistic culture favored, while Protestant-Puritan cultures resisted,

its development. The argument does not go beyond the author's earlier statement (*Quarterly Journal of Economics*, November 1953) and J.P. Henderson's cogent criticism of the thesis (*ibid.*, November 1955) is not answered or even mentioned. Bernoulli, Bentham, and Gossen receive generous treatment as pioneers of marginal utility theory, but of the three founders of modern utility theory, Menger alone is examined in detail. Indeed, the chief contribution of this book to the history of economic thought is the light which it throws on Menger's intellectual development: the author examined Menger's personal library deposited at Hitotsubashi University and discovered a large number of valuable annotations and notes in Menger's own hand.

The last half of the book is devoted to the development of marginal utility theory between 1880 and 1947, organized around certain central topics that appeared again and again in debates, such as the definition of rationality, the relation between costs and utility, the validity of a law of diminishing marginal utility of income, the measurability of utility, and the like. The author's exposition of these issues lacks analytical clarity and at times is downright confusing. For example, the discussion over the imputation problem is presented without a single reference to the fact that the Austrian writers dealt exclusively with the case of fixed input-coefficients and, hence, could not resort to marginal productivity considerations. And to put game theory in the same chapter as Wieser's theory of imputation, on the grounds that both theories are concerned with the division of a fixed sum among a number of participating agents, is hardly calculated to illuminate the theoretical issues involved.

M. BLAUG

Economic History; Economic Development; National Economies

The Conquest of the Material World—Essays on the Coming of Industrialism.

By JOHN U. NEF. Chicago and London: Chicago University Press, 1964. Pp. xii, 408. \$8.95.

It is a pleasure to be able to reread consecutively the series of beautiful essays Professor Nef has published over the last thirty years. They contain solid and purposeful research, original ideas, and stimulating polemics. Since the individual essays first appeared as self-contained pieces, the volume is in some measure repetitious; but this should not bother the reader, as the restatements help to emphasize the unifying thesis which runs through the book: the significance of the industrial upsurge in England during the hundred years between 1540 and 1640, which the author describes, somewhat waveringly, either as the "major rehearsal" for the "elder Toynbee's industrial revolution" which began in the last decades of the 18th century or as the "real" start, of which the later development was but a natural and not more impressive continuation.

The collection is introduced by an essay on "Mining and Metallurgy in Medieval Society" which is an illuminating and far-ranging piece, even though in

his eagerness to stress the rising dominance of the Continental Renaissance governments over the extraction of metals Nef tends to play down—unjustifiably and unnecessarily—the immense contribution made by South-German capital, not just to the financing, but to the technological progress in mining and metal-making. In the concluding part of the volume, the essay on “Genesis of Industrialism and Modern Science” makes some interesting, though perhaps somewhat superficially treated, points on the different position of science in England and in France, and particularly on the differences in orientation of French and English mathematicians in the 16th and 17th centuries; however, not much more emerges than the appearance of mere simultaneity, rather than of any intimate connection, between progress in industry and science of the period. Not everybody will be able to appreciate the alternatives of the epilogue with its assertion that religious faith is more important than the fruits of scholarship for “the things that are closest to our hearts” and that the danger of pseudoscientific beliefs is greater than that of dogmatic perversions of true religion. These pages will be read with respect as an expression of deeply felt personal views and of the urgent need for simple absolute truths in a world of relativism where any one of the very uncivilized “civilizations” and very uncultured “cultures” is readily regarded as a civilization or a culture. But the relation of those things to the essays is tenuous, save perhaps for Nef’s sense of loss of spiritual and aesthetic values that occurred in the process of “conquering the material world.”

The heart of the book lies in the comparison between English and French industrial growth from 1540 to 1640. The main fact of a rapid spurt in England, centering upon mining and “heavy industries,” is very convincingly established. The attempt to assess the quantitative differences in the rates of growth and volumes of per capita industrial output is somewhat less successful. Although a good deal of factual material is adduced, it is on the whole impressionistic (especially for France), so that very precise questions receive rather tentative and imprecise answers. The clearest case for England’s advantage over France is that of coal output, an area that no one is better qualified to treat than Nef, the author of a classic monograph on the subject. With regard to other branches of English industrial endeavor, modern research has arrived at less impressive results. On the whole, it appears very likely indeed that, during the period, England’s industry grew at a faster clip than that of France. Whether, as Nef believes, English industrial output by 1640 came to equal that of France is much less certain.

In interpreting his results, Nef is rather skeptical about attributing much importance to the spiritual effect of Protestant doctrines. He sees the main effect of the Reformation upon growth in the dissolution of monasteries, which transferred lands, rich in coal and iron ore, into private hands that were eager to exploit the resources, as well as in a basic change in the nature of demand. The demise of the Roman Catholic Church reduced the demand for “things of beauty” and created a “vacuum” filled by the new demand for utilitarian goods. This change in general economic orientation from “beauty to utility,” from “quality to quantity” Nef regards as crucial for the emergence of modern industrialism and considers it more revealing than any measurable dimen-

sions of industrial progress. Incidentally, while Nef the scholar continues pounding on the significance of the change, Nef the individual keeps deploring it, and at one point even raises the remarkably inappropriate question as to whether the beauty of a modern automobile can stand comparison with a medieval cathedral, a painting of Botticelli's, or a play of Shakespeare's.

Nef's well-known attack on the Hamilton-Keynes thesis, "Prices and Industrial Capitalism in France and England," has been included in the present volume, and rightly so since it, too, deals with the origins of "industrialism" and has an important bearing upon the comparisons of industrial growth in the two countries. The thesis claimed that the influx of precious metals and the resulting price revolution with its lag of wages (the "profit inflation") were largely responsible for the economic upswing of the period. Nef questions the validity of this monetary explanation, just as earlier in the book he was much too reluctant to attribute the depression of the 14th century to the exhaustion of easily accessible silver mines on the Continent. Nef certainly succeeds in showing that the picture was much more complex than Keynes presented it in his *Treatise on Money*. As Nef argues, the indices used by Keynes tended to exaggerate the fall in real wages. Some portion of the laborer's wage was paid in kind; some of the laborer's foodstuffs came from his own plots of land; the soaring timber prices may have raised the cost of production above the general level of prices; bread prices did not rise as much as grain prices; and, above all, France, which showed roughly the same degree of profit inflation, did not experience an upswing comparable to that of England. It would seem that Nef has been indeed able to cast some doubt on the thesis, but has hardly succeeded in refuting it. Some of his points are telling, others are obviously weak. If prices of bread—and beer—rose somewhat less because (as Nef claims) of cost-reducing technological improvements, this would mean that the wage earners' levels of consumption fell less than Keynes's figures indicated, but it would also mean that it had become possible to sustain a larger number of industrial workers on a given quantity of staple foodstuffs. And it still remains to explore to what extent the new technology in milling and brewing, as indeed in industry at large, was not the result of investments first induced and then increasingly rendered possible by the "profit inflation."

Moreover, only the *extent* of the fall of real wages is in dispute. The fact itself is generally accepted. The available information shows that prices of cereals rose more than those of converted products, a natural enough effect in conditions of falling real wages. Nef comments on this circumstance by saying, "As the price of bread apparently increased more than that of other foods, it is possible that the poor replaced bread, cakes, and porridge to some extent by other kinds of nourishments, such as herrings, beef, mutton, eggs, cheese, and small beer" (p.253). This statement, which gratuitously disturbs the ghost of Marie Antoinette, almost certainly reverses the causal nexus. During the period, inferior goods showed higher price rises not only within the whole group of foodstuffs, but also within the group of bread grains (rye versus wheat, which incidentally may explain the plantings of rye on less suitable soils under the late Tudors); and elements of this pattern can be observed all over Europe from the shores of the Atlantic to the plains of Russia. In fact, it

s extremely rare that an economic historian can travel so far and so safely on so simple a hypothesis.

As far as the comparison with France goes, Nef does tend to shift the argument when he claims that the lower rates of growth in France despite a similar degree of "profit inflation" prove that the price revolution did not *inevitably* lead to a commensurate spurt of industrial development. Inevitability is not an operational concept in historical research and the thesis was not argued in these terms. There are, however, excellent reasons why England could utilize the opportunities afforded by the price revolution more effectively than France. There is the absence of the religious wars that continued in France until the last decade of the 16th century. More important, however, is the basic fact of England's relative economic backwardness at the start of the period. As Nef himself points out, England's "concentration of capital in mining and metallurgy from 1540 to 1640 was stimulated by the application of technological processes introduced with the help of skilled foreign artisans" (p.132); the blast furnace probably came to England from France (p.177). And the area of productive borrowings from abroad was not confined to mining and metal making. France, much more advanced, had no comparable possibilities at her disposal. Similarly, the English stress on "utilitarian" goods, of which Nef rightly makes so much, is in general a characteristic of modern industrializations in conditions of backwardness. At any rate, such differences in the rate of growth as existed between England and France are unlikely in themselves to detract from the Hamilton-Keynes thesis. As far as the latter is concerned, we now have some studies dealing with the problems involved, and a great deal more research is necessary which will have to utilize very thoroughly for a larger number of countries the mass of price information which has been collected since the publication of Nef's paper nearly 30 years ago. But whatever the final judgments, there is no doubt that all such research will greatly benefit from the probing questions raised by our author.

Harvard University

Postwar Economic Growth: Four Lectures. By SIMON KUZNETS. Cambridge, Mass.: The Belknap Press of the Harvard University Press, 1964. Pp. 148. \$4.25.

This little book contains Simon Kuznets' Haynes Foundation Lectures of 1964. It is a book about postwar economic growth viewed in the very broadest perspective. It is concerned, of course, with the pace of postwar growth and its more narrowly economic causes. It is still more concerned, however, with the wider conditions and concomitants of the growth process. It therefore reaches into the political and institutional arrangements under which contemporary growth is taking place and considers the consequences which probably flow from the arrangements which have been either necessarily or fortuitously adopted. In developing his very wide themes, Kuznets brings to bear something like the full range of experience relevant to modern growth, that is, the

historical record of the developed countries going back into the nineteenth century and the international diversity present today in the developed non-communist countries and the developed communist countries as well as in the numerous underdeveloped countries still trying to launch themselves into the growth process under a variety of institutional forms.

The variety of issues on which Kuznets at least touches matches the range of experience he considers, and it would be quite impracticable—as well as uninteresting—to try to catalogue them. A recurrent objective, however, runs through the book. This is to trace the consequences of heightened interdependence among people and nations in a world rendered increasingly diverse by economic growth and by the forms of organization adopted to achieve it. The potentialities of both cooperative interchange and violent conflict have been dramatically enlarged by progress in the means of transportation and communication. And while the desire for economic growth and the efforts to foster it have become more intense and worldwide in range, the incidence of growth has been very uneven, and the distribution of people with respect to levels of living and productive power has tended to widen rather than to narrow. To this important element of diversity, one must add another. The systems of social and political organization through which nations seek growth have also become more diverse. The question Kuznets appears to pose, therefore, is this: are there in the growth process, with its concomitant tendencies to interdependence and diversity, the potent seeds of domestic and international strain and conflict? Kuznets' answer is yes. His view of the matter, all too briefly and categorically stated, runs somewhat as follows.

The desire for modern growth and for the material rewards it promises has now spread to all peoples. Modern growth, however, involves a familiar, but nonetheless radical, transformation in the economic and social structure of countries, a transformation which goes on as long as growth takes place. To carry through the required transformation on a sustained basis over many years demands a government sympathetic to the expansion of economic activity and strong enough to sanction, protect, and cushion the many readjustments of social relations implied. Such governments have hitherto been national in character and nation-states have proven, so far, to be the only practical and effective units capable of organizing the necessary apparatus of power and decision. The spread of the desire for economic growth has, therefore, been matched by the proliferation of independent nation-states.

In principle, it might be that nation-states and their national governments could work together in harmonious cooperation. Concomitant influences, however, some of them intimately involved in the growth process itself, decree otherwise. Modern growth started in one country, was taken up by a few others and then spread in widening circles throughout the world. In short, the time of entrance of different countries into the process was uneven. Great disparities have, therefore, resulted in the pace of economic advance of different countries which, sustained over several decades, successively revolutionized the balance of economic and military power. The countries that were advancing understandably wished to exploit the advantage offered them by a new balance, while others, just as understandably, attempted to resist the change. Wars

were, and are, a natural consequence, and the occasions for war are only multiplied by the readjustments of political spheres implicit in the break-up of colonial empires, a break-up itself required by the need to establish national governments as a basis for economic growth.

Not only war, but world war of unprecedented destructive power, appears to have been a concomitant of modern growth. The great progress in transportation and communication which intensified the economic ties among countries also tended to create large blocs of interdependent countries. Capital flows required to promote growth among laggard countries made for relations of dependence. The same progress in transportation and communication, combined with much higher productive power, meant that when war came it could involve large numbers of men and great volumes of equipment sustained in combat at distant bases for long periods.

Finally, Kuznets notes that while national governments have hitherto proved to be a prerequisite for growth, governments organized on a variety of systems and enforcing a variety of forms of political and economic organization appear to be compatible with growth. We, therefore, find national governments presiding not only over democratic capitalist systems but also over communist dictatorships or party oligarchies, as well as other varieties of organization. The conflict of rival systems then enters to complicate and aggravate the conflicts inherent in adjusting political influence to a changing balance of economic power.

Kuznets does not present his views as baldly and schematically as I have done, and my statement may do him an injustice. In any event, it is clear that he does not see economic growth as the sole source of domestic and international strain and conflict. There are other sources of divisive nationalism besides economic growth and other sources of war between national states besides shifts in the balance of economic power.

As already said, the recurrent theme sketched above is only the leading motive in a score rich in other material. To mention only two: there are suggestive discussions of the costs and consequences of World War II in their bearing on economic growth, and there is a brief, but balanced, presentation of alternative interpretations of the generally rapid postwar growth rates and of the contrasting postwar growth records of different countries.

These lectures afford economists a chance to become better acquainted with Kuznets in a less familiar mood, not in his empirical, but in his interpretive aspect. Few economists dare to leave the borders of economics and the security of statistical measures. Few who do can bring to their excursions Kuznets' historical perspective and imaginative reach, and these lectures suggest that the man who has given us so many solid statistical monographs is equally at home in the speculative essay.

MOSES ABRAMOVITZ

Stanford University

The Economics of the Developing Countries. By HLA MYINT. New York: Praeger, 1965. Pp. 192. \$3.00; paper, \$1.95.

The book-length literature in economic development has tended to divide

into two very different classes: into compendia of economic analysis, often speciously sophisticated, whose purpose is as much to plead the theoretical respectability of the field as to tackle the real problems of development; and into popularizations, usually empty of analysis, which move monolithically to the conclusion that the problems either are practically intractable or really require no more than some simple reorientation. Refreshingly, Professor Myint's work avoids both these extremes, and while brief, it is comprehensive, beautifully written, and analytically sound.

Its brevity, however, somewhat limits the audience for the book. Its very conciseness makes the problems appear too simple and the conclusions too obvious to permit its use as a primary text, though parts should prove useful supplements to both graduate and undergraduate reading lists. On the other hand, little will be learned by the development economist who has long since assimilated Myint's seminal articles of the 1950's and has kept up with recent controversy. The most appreciative reader undoubtedly will be the general economist who would like to know what this field called "economic development" is all about and where current thinking in it is leading.

The book consists of two quite distinct parts. In the first half, Myint reviews the process by which the African and Asian countries were absorbed into the world economy and the reasons why they failed to achieve steady growth. These chapters are basically a synopsis of Myint's three famous "backwardness" articles (*Oxford Economic Papers*, 1954; *Review of Economic Studies*, 1954-55; and *Economic Journal*, 1958) and will solve for many a teacher the dilemma as to which article to assign his students. Now as before, Myint deals chiefly with the "semi-empty," as opposed to the initially overpopulated, countries and focuses primarily on the growth of export crops and of foreign-dominated mines and plantations. Two welcome extensions of the earlier writings are the greater concern for the monetary aspects of the process and the clearer picture of the time-dimensions. Not so welcome is the greater emphasis on the "cheap labor policy" of foreign entrepreneurs on which Myint puts most of the blame for the failure of the "opening-up" to lead to sustained growth. Certainly he goes too far in suggesting that the vastly higher rates of growth in North America and Australasia were caused by their "conventional standard of high wages" (p. 57).

The next four chapters of the book are largely a critical analysis of what Myint feels are the false shibboleths of development policies. One by one, he attacks the relevance of the disguised unemployment concept, savings-oriented growth theories, the adequacy for planning of the aggregate capital-output ratio, the critical-minimum-effort thesis, the need for a big-push, balanced growth arguments, the "self-destroying" nature of deficit finance, the declining world demand for primary products, and the desirability of across-the-board protection for domestic manufacturing industries. Needless to say, with so many targets and only 80 pages for all, but a few lashes can be devoted to each. It is inevitable that some of the criticisms are now well known, the more so since Myint's views are closely attuned to recent trends in development literature. Nevertheless several of the strokes are remarkably well directed. Readers with stomach left for the balanced vs. unbalanced growth controversy

will find Myint's classifications of the different strands of the theory particularly lucid, and his discussion of trade policies is excellent.

Although the book is marvelously coherent and instructive throughout, the reader will probably feel disappointed at the end on two counts. One, the early chapters on the failure of the "opening-up" to bring about sustained development in the African and Asian economies are not well integrated into the subsequent discussions of development policies. While knowledge of the causes of backwardness in no way insures knowledge of its cures, one would have hoped that Myint's unique insights into the historical process would have led him to specific policy recommendations, perhaps even have guided his entire thinking about development policy. And two, the generally critical tone of the later chapters makes it difficult to recognize Myint's positive contributions. While the final chapter is intended to "bring out the implications of my analysis" (p. 166), it in fact goes on to new material (i.e., the role of markets, educational policy, and foreign aid).

While *The Economics of the Developing Countries* offers little that is new, it is always useful to know where a man of Myint's stature stands. More important, the book is so concise, so clear, and so in tune with general thinking that it will provide a valuable benchmark of the state of economic development theory at the mid-1960's.

RICHARD C. PORTER

University of Michigan

Principles of Development Economics. By HENRY J. BRUTON. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1965. Pp. viii, 376. \$7.50.

Textbooks on economic development tend to be full of anecdotes, colorful examples, peculiar special cases, and tables listing economic features of remote lands. Professor Henry J. Bruton has written a text without a single footnote, without a single table giving data on underdeveloped countries, and absolutely devoid of references to his travels abroad. What is he trying to accomplish?

Making some small modifications to the established body of neoclassical assumptions and analysis, Bruton tries to isolate key economic principles which are especially relevant to the "typical" underdeveloped country. Naturally, his approach will not please those economists who do not consider neoclassical economics and/or economic calculus relevant to underdeveloped countries, especially those who abhor the use of the production function, widely employed by Bruton throughout his book.

After a terse definition of the basic problem faced by developing economies (raising per capita income), the book proceeds to catalogue the main sources and mechanics of growth for any economy. This is done with the aid of the production function concept. Bruton's presentation of the neoclassical theory of production takes into account some of the criticisms levied against it. For example, he explicitly assumes that capital, once embodied in a machine adapted to a given technique, cannot be used in any other technique, and that only a few techniques of production are available to any single industry. His discussion of technological change also considers the possibility that techno-

logical breakthroughs achieved in labor-poor, capital-rich countries may force underdeveloped countries to choose between maximizing output or employment.

The first 80 pages of the book in effect provide the building blocks needed for growth models, although Bruton wisely refrains from presenting the properties of any specific model. Attention is given to the implications for growth of the existence of interdependent sectors, using the input-output table as a framework for the discussion. While a chapter is also included in this first part of the book discussing demand and pricing problems, the emphasis is on supply conditions throughout the volume.

After examining in general the sources and mechanics of economic growth, the author presents in one chapter the main features of a "typical" underdeveloped economy which accounts for its slow growth. This heroic attempt to summarize in about 30 pages the great variety which exists among backward economies is, of course, consistent with the emphasis of his book on economic principles instead of facts and figures regarding underdeveloped countries. Nevertheless, one wishes Bruton had included some sort of typology of underdevelopment, to make the student aware of key differences which exist among underdeveloped countries and the influence which such variety may have on the analysis.

Part II of the book is devoted to capital formation. This section starts with an explanation of "the optimal saving problem," and later on analyzes ways in which capital formation may be increased. These include the mobilization of unemployed labor, more effective use of existing capital, capital inflows and, of course, increasing saving. In this part of the book Bruton introduces some of his favorite themes and policies: the importance of an effective taxing machinery; the need for flexibility and "capacity to transform" in the economy; and the high potential pay-off awaiting a better allocation of existing resources. The sections dealing with the possibility that an economy may lack the transformation capacity to exploit fully its saving propensity are especially clear and well written.

The economics of the accumulation of technical knowledge and labor skills receive as much attention as the economics of the accumulation of physical capital. Part III of the book discusses these other possible uses of investable resources, treating the accumulation and application of knowledge as well as the accumulation of labor skills as just another economic process to which production function reasoning can be applied. The author admits that in these fields such reasoning becomes harder to quantify and apply, but argues that an attempt to use economic rationale is imperative lest decisions in these fields be left in the hands of politicians. In spite of one's sympathy for such a position, it must be granted that the "marginal return should be equated with marginal costs" advice flowing from the analysis tends to become formalistic and empty. In spite of this criticism, the more than 60 pages devoted to the two chapters dealing with technical knowledge and the training of labor contain much that is stimulating and instructive. The presentation in these chapters is generally straightforward; however, the discussion of the criteria for replacement of machines under conditions of technological change (pp.

197-200) is rather confused. After pointing out that sunk costs do not affect the replacement decision, the author goes on to use fixed costs as an element in the determination of when machines should be replaced when there are prospects of new and more productive machines being available in the future.

Part III of the book also includes chapters on the social environment of economic development and on population. It is argued that no single environmental feature is either essential or is an insuperable obstacle to the achievement of development, and emphasis is again placed on the need for flexibility if an economy is to exploit opportunities which are open to it. Bruton's views on population are strong, perhaps due to his experience in Asia: he claims that a conscious policy aimed at reducing the birthrate should be part of the development program. A typology of underdevelopment would have been useful in showing that for countries with relatively high resource/labor ratios (such as some Latin American and African countries), such a strong statement may be misleading.

Part IV of the book devotes two chapters to examining the criteria for the optimal allocation of investable resources. The emphasis is on showing that no simple rule of thumb will yield optimal results, and that one should fall back on maximizing the social marginal productivity of investments, modified to take into account all possible side and indirect effects, which for this purpose should be quantified as accurately as possible. The author explicitly asserts that no generalization is possible regarding the optimal sequence of investment by sectors of the economy (such as first agriculture, then light industry, etc.).

Bruton's approach to the economics of development becomes even clearer in the last part of his book, which deals with money and finance and strategies of development. Popular catchphrases and issues, such as the take-off, industrialization vs. agriculture, big push, etc., are criticized as highly simplified views of the problem of growth and as harmful to the understanding of the development process. The usual economic calculus, the author feels, is enough to tackle development problems without the need of grand generalizations. The discussion of the relation between inflation and economic development is lucid and well balanced, and avoids getting involved in the sterile debate between "monetarists" and "structuralists."

Bruton's approach will train the student to deal in a logical and careful way with the many false issues and misleading simplifications found in the field of development. In this respect, this text is to be welcomed most enthusiastically. However, rigor has a price, and in this case the price is absence of liveliness and occasional lapses into rather empty formalism. The book does not read easily and lacks the wit and charm of, say, Kindleberger's book on the same subject. At times Bruton seems perversely intent on making the book unnecessarily forbidding. Thus, in discussing input-output, instead of labelling his sectors as "Agriculture," "Industry," etc., he uses general notation which is likely to terrify an undergraduate. On page 12 he starts a discussion of the meaning and measurement of capital which may satisfy Mrs. Robinson, but which will leave the undergraduate a bit baffled. Perhaps a few footnotes with quaint anecdotes would not have been so bad after all.

Even an author so fully committed to presenting bare theoretical bones as Bruton is, cannot, when writing a text on development, wholly put aside his favorite policy biases. At several points in the text, statements in support of some policies are made without much elaboration as to their rationale. Thus, in the middle of a chapter on demand and pricing problems, it is stated that: "The achievement and maintenance of export markets may depend to a very great degree upon the ability of the developing country to provide the world with new products" (p. 68). In the chapter on "the nongrowing economy" it is flatly asserted that: "To parcel out titles to plots of land to individual peasants who have no access to credit, seeds, fertilizer, or water except from their landlord will surely create nothing but chaos" (p. 118). Two more examples of *obiter dicta*: "But control and red tape do not seem to have the economizing effect that simply a high price has. Also, controls and red tape are frequently best tolerated by persons least concerned with productive investment" (p. 138). "(Indeed one may go further and assert that improving the tax system is the single most important task confronting the government of the underdeveloped country)" (p. 155).

Foreign trade is regarded throughout most of the text as just one more line of economic activity of the underdeveloped economy, with no specific peculiarities. Bruton deems that exhorting the underdeveloped economy to increase the transformation capacity of its economy and to set the price of foreign exchange equal to its social opportunity cost is all that needs to be said to a country complaining about foreign exchange shortage. The optimal pattern of foreign trade can be determined in the same way as allocation within the economy, naturally using taxes and subsidies to eliminate divergences between private and social costs and benefits. This handling of foreign trade highlights the virtues as well as the limitations of this text. It provides an excellent general framework for the analysis of development problems, but is likely to leave the student a bit cold and uninformed about several policy questions and historical patterns of trade and growth. Besides this skimpy treatment of foreign trade, the text discusses only briefly issues related to foreign aid.

A substantive criticism may be made of one of the themes of the book. In several places Bruton points out that in underdeveloped countries it is common to find overvalued exchange rates and interest rates which are below the equilibrium rate. He asserts that this leads to misallocation of resources by encouraging the use of "too many imports" (p. 106) and of capital intensive techniques. Yet, the fact that lucky holders of exchange permits and beneficiaries of the subsidized loans of state banks can get part of their foreign exchange and credit needs at rates below those which rule in competitive markets does not necessarily lead these entrepreneurs to use them as if they had unlimited access to the subsidized resources. Indeed, they are likely to be fully aware of the true scarcity value of these rationed resources. Thus, while controls may create windfalls for the groups favored by the authorities, it is doubtful that they will induce the favored entrepreneurs into using "too many imports" or "too much capital." In fact, of course, overvalued exchange rates lead to "too few" imports in the long run via their impact on exports; this is certainly a misallocation of resources, but not of the type described by Bru-

ton. The policy of rationing foreign exchange and credit by using controls rather than equilibrium prices could even be partially defended on the grounds advanced by Bruton in his discussion of the policies required to induce the most "suitable" form of technological change in underdeveloped countries. As he points out (p. 193), it is well known that if the supply of all factors is perfectly elastic to the individual firm, there will not be an incentive for these firms to give any bias to their technological change. Rationing of foreign exchange and of credit would thus help to give a bias to technological change in favor of capital and foreign exchange saving, presumably the "right" type of bias to have in the underdeveloped economy.

The over-all judgment on this book depends very much on the views of each teacher on the best way to introduce the student to the economics of development and on what development economics should be all about. In spite of the minor criticisms made above, the reviewer's biases on these issues are very similar to Bruton's, and thus I would consider his book one of the best available texts in the field. The teacher using it will have the additional windfall of holding a monopoly on anecdotes and colorful examples.

CARLOS F. DIAZ ALEJANDRO

University of Minnesota

The Morphology of Greek Industry—A Study in Industrial Development.

By GEORGE COUTSOUMARIS. Research Monograph Series No. 6. Athens, Greece: Center of Economic Research, 1963, Pp. viii, 430.

The Center of Economic Research in Greece was established to provide: "(1) basic research on the structure and behavior of the Greek economy, (2) scientific programming of resource allocation for economic development, and (3) technical-economic training of personnel for key positions in government and industry." *The Morphology of Greek Industry* is a policy-oriented, empirical investigation of the structure of Greek industry, stimulated to a considerable extent, it appears, by the association of Greece with the European Common Market and the policy problems involved in development within that framework.

The book is divided into three principal parts, with an appendix of 54 pages of statistical tables. None of the main parts is entirely morphological; some attention to the performance and functioning of industry as well as some description of government policies toward industry are interwoven throughout the book. Part I, however, is largely statistically descriptive, with chapters dealing with the number of producing units by industry, output and employment size distributions, characteristics of industrial demand, locational patterns of industry, investment and capital-labor factor mixes, cost structures, and forms of business and financial organization. Part II deals with economic performance as measured by rates and patterns of growth, factor productivity and factor returns, and indicia of scale economies. Part III views the development outlook including an assessment of the probable effects of the Common Market in Greece, and some policy conclusions.

The detailed statistical findings cannot be indicated here. Greece, after

rapid industrial expansion between 1923 and 1939, has a manufacturing sector which accounts for less than 20 per cent of its gross domestic product. The industrial structure has in general changed little since 1930 and is characterized in most industries by small manufacturing establishments and, especially in textile, clothing, and footwear production, by large numbers of home-establishments. Only three-tenths of one per cent of the manufacturing establishments had 100 or more employees in 1958, and multiple establishment firms are rare in most industries. It is concluded that manufacturing suffers from "considerable diseconomies of scale" and that horizontal mergers would lead to greater efficiency.

Household demand for manufactured goods, measured with cross-section data, is found to be generally income-inelastic, though the elasticity between manufacturing output and net national income, based on time series, is income-elastic. The author argues that because of these elasticities, the expansion of industry will depend on developments in producer inputs and capital goods which might reduce costs and prices for "wage goods" and, in turn, release demand for the expansion other sectors.

Industries which are "raw-material oriented" (e.g., food processing) are geographically dispersed while those which are "market oriented" concentrate in a few urban centers—Athens in particular. George Coutsourmaris is critical of government policies favoring decentralization because of their failure to take account of optimal location patterns and to coordinate the over-all development planning.

Capital-output coefficients are typically higher than those for U.S. industries, a phenomenon which is said to reflect underutilization of capacity and high inventory requirements of an inefficient marketing system. Capital-labor ratios and ratios of the wage bill to capital amortization, interest, and profits are computed also, but few conclusions are drawn from them. Following a description of the asset composition of firms and sources of investment funds, Coutsourmaris provides an interesting analysis of capital markets and the extent of corporate enterprise, indicating several impediments to the growth of larger-scale enterprise and to development generally. That larger enterprises, the development of external economies (e.g., power, transportation), and improved tariff policies are essential is supported by studies of cost structures and interindustry relationships.

Part II, "Economic Performance," places these findings in historic and international perspective. It is concluded, perhaps too optimistically, that Greece is "on her way toward a second stage of industrial development in which manufacturing output approaches a balance between consumer and producer goods." But changes have been slow because of narrow markets, political and economic uncertainties, and inappropriate government policies. Productivity, while rising, is low in absolute terms due to scale inefficiencies, the use of inferior technologies, an inefficient industrial organization, inadequate managerial resources, government intervention, and market imperfections.

In the concluding part, the outlook is presented in terms of projections based on recent experience with national product growth rates and the relevant income-elasticities. It is then noted that entry into the Common Market will require growth in areas in which comparative advantage exists, and these

are held to be material-oriented industries, labor-intensive, transport-extensive industries, regionalized industries, and intermediate-product industries. The size of the market for some Greek industries should thus grow; others will experience increased foreign competition and probable contraction. Greek labor, which has already flowed to European markets, could be joined by Greek capital seeking higher returns, and both could have retrogressive effects. Association with the Common Market, that is, makes the demands for economic reorganization even more pressing. The short section on policy conclusions indicate steps to speed such reorganization, the nature of which is anticipated by the previous discussion of the sources of inefficiency.

Coutsoumaris has presented an admirable statistical tableau of the economic structure of his country, descriptions of its weaknesses and prescriptions for their cure. Yet reading it—and the recent news of political events—hardly leads to sanguine expectations.

ALMARIN PHILLIPS

University of Pennsylvania

Chile: una economía difícil. By ANÍBAL PINTO. Mexico City: Fondo de Cultura Económica, 1964. Pp. 184. 16 pesos.

Aníbal Pinto is a prolific Chilean who has published many books and articles on economic matters: e.g., *Finanzas públicas*, *Hacia nuestra independencia económica*, *Chile: un caso de desarrollo frustrado*, and *Cuestiones principales de la economía*. He has been a professor of fiscal policy in the University of Chile; founder and president of the Chilean Economic Association; founder, director, and editor of the Chilean economic review, *Panorama económica*; director of the journal of the Faculty of Economics of the University of Chile; and one of the project directors of the Chilean Economic Institute. Along with all this, he has taken an active part in the work of the Economic Commission for Latin America of the United Nations.

In the United States, a person with all these accomplishments would, in all likelihood, be an economist. In Latin America, things are not that simple. Pinto was a law student when he fell ill and, like Ricardo at Bath, read a bit of economics for diversion. The subject interested him; he continued to read it; and finally obtained a year's scholarship at the London School of Economics. In this way he joined the sizable group of Latin Americans who are considered economists "autodidacta." Since Smith, Ricardo, and Harrod were also largely self-taught, the propriety of considering such a person to be an economist must rest on the quality of his work.

In assessing Pinto, the present work may be taken as typical. It began as a set of notes for some lectures on the Chilean economy from 1950 to 1963. The lectures were never given, but the notes became the basis for a broader study of the current problems in economic development and Chile's prospects for the future. Pinto uses the word "difficult" in order to get away from the semantic and ideological overtones of "rich" and "poor," "developed" and "underdeveloped." He insists (p. 84) that it is more sensible to agree that the Chilean economy is difficult than to argue endlessly about its richness or poverty. While accepting that the same can be said of many other economies, he points

out that the Chilean economy is small and has reached the end of the "easy stage" of import substitution, and that the Chilean social and political structure is responsible for all sorts of complications in the process of economic development, many of them unknown. The solution suggested is the discovery of a "more complicated model" of economic development which would combine "the complete transformation of the economy, a new type of 'opening' to the outside world, the achievement of greater autonomy in its workings, and—last but not least—a distribution of resources and income which would take into account and satisfy the aspirations of that sizable part of the population which has, up to now, remained at the margin of the development process in the last decades" (p. 10).

The problem posed is respectable enough, but Pinto's analysis is not quite adequate. The argument proceeds on a level of rigorous superficiality. Whenever things begin to get interesting, he throws up his hands and moves on to another point, either because the data for a proper discussion are lacking or because there "is not time" for a longer exposition:

As the Institute study frankly states, one of the most serious omissions in the data is that referring to the changes in income distribution. The only reason for that is the refusal of the responsible institution, the Development Corporation, to release the official figures covering the years after 1954 (p. 40).

Most of the data concerning industrial production do not lend themselves to a detailed examination of the problem (p. 46).

With respect to the problem of relative prices, the global figures on hand do not help analyze the problem or shed much light on it, either (p. 48).

It is not possible on this occasion to inquire in detail into the causes of this phenomenon [weakness of investment], the importance of which in the development process must be emphasized (p. 56).

We cannot analyze the problem [sources of funds] in detail (p. 115).

The problem [of stability] has been debated *urbi et orbi*, and we cannot consider all of the arguments about it (p. 116).

It hardly requires excuses to confess that we cannot make any further progress in the analysis of these questions [foreign trade] (p. 128).

Then, when statistics are actually produced, they are presented in tables full of careless errors: units are cited when thousands of units are meant (p. 108); some columns have no headings at all and are quite meaningless (p. 48); while, in other tables, several columns have the same heading but contain different figures (p. 51). The text itself appears to have been dictated or written at high speed. It abounds in clichés and repetitions. But, once the reader understands that the author is not a trained economist or a prose stylist, the book can be read with profit. It presents the same sort of interesting, but hardly penetrating, description of a country's economic problems that magazines like *Vision* or *Newsweek* occasionally publish. They do nicely until a proper study can be completed.

Economic Systems; Planning and Reform; Cooperation

Techniques of Economic Forecasting. An Account of the Methods of Short-Term Economic Forecasting Used by the Governments of Canada, France, the Netherlands, Sweden, the United Kingdom, and the United States (with an introduction by C. W. McMahon). Paris: Organization for Economic Co-operation and Development, 1965. Pp. 173. Paper, \$3.75.

Quantitative Planning of Economic Policy. A Conference of the Social Science Research Council Committee on Economic Stability. Edited by BERT HICKMAN. Washington: The Brookings Institution, 1965. Pp. xiii, 279. \$7.95.

Economic planning is a field which is almost as broad as all of economics. Since a plan is an expression of the wishes of the policy-makers there arises at the very onset the problem of formulation of a preference function. The preferences must be translated into policy objectives which require the construction of a (explicit or implicit) model of the economy. To find out how best to achieve the objectives it is necessary to make conditional forecasts of economic development; to make the forecasts, a knowledge of quantitative relations within the economy is needed. If plans are to be implemented, the economists must be aware of the political and administrative processes within the economy. If successive plans are to improve, an appraisal of past performance and an analysis of the causes of failure are essential.

The complexity of tasks and the multiplicity of talents which are required make collective publications particularly welcome. Much can be learned through a comparison of experiences of different economists dealing with similar problems, as well as from the comparative treatment of various aspects of the planning task. The two volumes under review rely, respectively, on the two approaches. The OECD concentrates on short-term national forecasting, which is an indispensable building block in the formulation of national short-term plans and policies. The Brookings Institution collection looks at a whole gamut of planning problems, from the formulation of policy-makers' preference functions, through econometric model-building, to a reconciliation of the approach of the mathematical economist-planner with that of a pragmatic policy-maker.

Both volumes draw on international experience. The OECD gives an account of short-term forecasting methods of the governments of Canada, France, the Netherlands, Sweden, the United Kingdom, and the United States. Of the eleven chapters of the Brookings volume, five discuss national planning experience. Of these two are devoted to the Netherlands, two to Japan, and one to France.

The two collections give the reader a vast menu to select from, and they contain some excellent morsels. Unfortunately these morsels do not amount to much of a meal. As in most reprints of conference papers, there is a lack of common purpose and of a uniform standard which would make the separate pieces add up to an integrated whole. The editors of the two volumes fought valiantly to forge unity out of confusion and to draw some general conclu-

sions (the palm goes to C. W. McMahon who performed a tour de force in writing a clear and concise summary of the achievements and problems of short-term forecasting incorporating the information given in the various national essays) but, short rewriting the component essays, they had to satisfy themselves with a limited success.

Take the OECD volume. The purpose of putting together the experience of six countries is, presumably, to permit a comparison of the success of the various national forecasting techniques. The degree of success of applying method X to country A cannot be readily compared with the degree of success of applying method B to country Y. Ideally one might want to see the results of application of diverse techniques to a single country, or of a single technique to diverse countries in order to learn something about forecasting methods as well as about the problems of forecasting under diverse institutional systems. Since the papers relate national experiences, one could hardly hope that any of them would undertake such a formidable research task. However, it would not be too much to ask for a uniform exposition of the methodology and at least some discussion of the success of forecasts using, if possible, comparable methods of measurement of forecast fit. Even this more modest requirement is far from being satisfied.

Of all the papers the one on Sweden comes closest to telling the reader how the forecasts are made and how good is the fit. The exposition is lucid and informative, though it would gain from a comparison between the results of the final forecast and of the econometric forecast which is run as a sort of a check on the more informal procedure used by the government. The Dutch who have spent years on model-building and on rigorous testing on forecasts have contributed a very skinny paper. The reader would learn much more by turning to C. A. Van den Beld's admirable essay in the Brookings volume.

The Canadian essay shows how and why things are done in that country, but some crucial questions are left unanswered. For instance we are told (pp. 47-50) that the forecasts utilize the results of a periodic capital investment intentions survey. A chart on page 49 shows that the survey has a systematic bias, but it is never revealed whether the forecasters try to correct for the bias or whether they accept its presence with fatalism. No attempt is made to discuss the fit of the forecasts.

The other essays are much less informative, with the prize going to the five-page piece on French forecasting. It may be noted in passing that Mr. Cazes's piece in the Brookings volume which deals with long-term features of the French plans is equally unrewarding. What the French planners say in fact is: "we are giving to our patient an excellent patent medicine called 'active planning.' It contains input-output tables, target figures, horizontal and vertical commissions and several secret ingredients. As the chief doctor, M. Massé, has said in a recent *Econometrica* article, the question to what extent are French plans implemented is 'ambiguous.' Moreover, we should not ask whether the medicine does good or whether it harms the patient, because the unshaken belief in its efficacy is an essential condition for the medicine's success."

The high point of the Brookings volume is reached almost at the start. In

Chapter 2, Professor Theil gives a lucid, accessible, yet profound discussion of the problem of "Linear Decision Rules for Macrocynamic Policy Problems." The essay manages to show in twenty pages the advantages as well as the weaknesses of a quadratic preference function for policy-making purposes, and demonstrates how the method applies to short-term planning.

Two theoretical chapters by Karl A. Fox and Erik Thorbecke and by Jati K. Sengupta show that the authors have looked at many short-term forecasting and policy models and that they are well acquainted with the arcana of latest econometric thought. The few readers who are expert econometricians will, doubtless, disagree with this or that point, but will find most of the treatment sound if not very novel. The many whose econometric training is deficient will realize how much learning it requires just to understand what the authors say, let alone compete with them. For the authors it was doubtless useful to write down a concise summary of their knowledge. The readers will primarily benefit from the copious footnotes.

A bridge of sorts is provided between theoretical model-building and practical planning policies by E. S. Kirchen and Lucian Morrisens who have provided a chapter on "The Objectives and Instruments of Economic Policy" based largely on a collective work entitled *Economic Policy in Our Time*. The chapter catalogues all the familiar policy goals (full employment, balance-of-payments stability, etc.) and all the familiar policy instruments, and does very little else. The closing chapter by Charles C. Holt entitled "Quantitative Decision Analysis and National Policy: How Can We Bridge the Gap?" is much more rewarding. It shows what are the possibilities as well as the limitations of quantitative planning in the context of policy-making by the U.S. government.

If the reader learns anything from the Brookings Institution volume it is that the Dutch are at the forefront of the theoretical as well as practical work on short-term planning. Theil's discussion of the formulation of a policy-makers' preference function should be read in conjunction with William Hessel's "Qualitative Planning and Economic Policy in the Netherlands" (Chapter 7 of the collection) in which it is shown how conditional forecasts are used in arriving at a policy consensus. Van den Beld's chapter on "The Short-Term Planning Experience in the Netherlands" tells in detail how the conditional forecasts are made, and evaluates the results of policies. This sort of unity (which should have permeated the whole book) is marred by some minor discrepancies in treatment. For instance in Van den Beld's essay the 1956 economic situation and the 1957 forecast are presented (on p. 155) in 1956 prices, and in Hessel's essay (on p. 171) in 1955 prices. Van den Beld discusses the targets of the Central Planning Bureau (which on p. 155 are mistakenly labeled as "Effects of the Program on 1957 Outcome"), whereas Hessel deals with the targets of the Social and Economic Council which were changed before being incorporated in the plan. The relations between the two sets of targets are never made clear. The resulting confusion could have been eliminated through more careful editing.

If any reader needs to be convinced that in some countries there is a vast

gap between the theory and practice of economic planning, he should turn to the two chapters by Shishido and Watanabe, which show how the Japanese economy has been steadily running away from the planners. The Japanese plans have been overcautious and poorly "balanced," and they have had very little impact on the country's development. Whether the Japanese economy suffered or benefited from the lack of planning is something of a moot point.

Both the OECD work and the Brookings volume have useful references, and the Brookings volume has an index.

Economic Policy in Our Time. By E. S. KIRSCHEN AND ASSOCIATES. Vol. I: *General Theory*; Vol. II: *Country Studies: United States* [O. Eckstein], *United Kingdom* [F. Blackaby], *and Norway* [J. Faaland]; Vol. III: *Country Studies: Belgium* [L. Morissens], *Germany* [H. Besters], *the Netherlands* [F. Hartog], *France* [J. Benard], *and Italy* [E. Tosco]. Chicago: Rand McNally & Co.; Amsterdam: North-Holland Pub. Co., 1964. Pp. 474; 224; 482. \$12.50; \$6.00; \$12.50.

Volume I attempts to generalize the practice of economic policy in eight Western countries between 1949 and 1961. It is accompanied by two volumes reporting actual measures taken. Readers will be disappointed if they expect an expansion or new explorations along the frontier of the theory of economic policy scouted so admirably by Jan Tinbergen nearly a decade ago.¹ However, nothing in economic literature approaches the present authors' threefold aim: (i) to classify the instruments and objectives for a large and representative part of Western economic history since World War II; (ii) "to compare and contrast the economic policies actually followed in our countries since 1949"; and (iii) "discuss the ways in which policies are in fact formed and difficulties of their execution" (Vol. I, p.v). These are admirably accomplished, but alas they aren't enough. The names of Professor Kirschén's associates create expectations which remain unfulfilled. By restricting their investigation to a taxonomical description of economic policies we are denied, as they acknowledge, learning anything new about the efficacy of policies and the economic mechanisms by which measures achieve aims. Their excuse for having stopped short of venturing into what economists generally consider their proper realm is they "had enough to do without it" and in doing so "would have had to reach agreed views on a number of the more disputed points in present-day economics. This would not have been practical" (I, p.vii). In sum, we are told only about the decision-making process and decisions actually taken, but virtually nothing about the time lapse before the actions achieved or failed to achieve the desired objectives, nor about the conflicts, interactions, and feedbacks within and between instruments and objectives. The book should be judged, of course, by how well it accomplishes its aims, but my disappointment is no less.

Volume I, subtitled *General Theory*, is the joint product of all nine authors. In Part I they use the terminology and framework of analysis developed by

¹ Jan Tinbergen, *Economic Policy: Principles and Designs*, Amsterdam 1956.

Jan Tinbergen and the postwar experience of the six Common Market countries, together with Norway, the United Kingdom, and the United States, to prepare a standardized classification of instruments and objectives "which will be suitable for any developed country with a capitalist or mixed economy" (I, p.v). Twelve objectives were chosen to describe the aims of countries between 1949 and 1961 (I, pp.5-6):

Mainly short-term (conjunctural)

1. Full employment
2. Price stability
3. Improvement in the balance of payments

Mainly long-term (structural)

Major

4. Expansion of production
5. Improvement in the allocation of factors of production
6. Satisfaction of collective needs
7. Improvement in the distribution of income and wealth
8. Protection and priorities to particular regions and industries

Minor

9. Improvement in the pattern of private consumption
10. Security of supply
11. Improvement in the size or structure of the population
12. Reduction in working hours.

Certainly every economist could question both the list's limitations (why are increasing productivity and rising real wages omitted?) and the distinction between essentially conjunctural and long-term, e.g., full employment and improvement in the balance of payments for the United States appear to require considerable structural change; but each reader would probably agree with the authors' desire to "keep the number of objectives as small as possible" (I, p.6).

The authors discuss five families of instruments: public finance, money and credit, exchange rate, direct controls, and changes in the institutional framework. All together, 63 instruments are enumerated as having been used between 1949 and 1961, serving the authors claim, 303 objectives.

"Considering the whole field of economic policy," they state, "the public finance family of instruments was the most important one" (I, p.148). This conclusion is based, like most of the others, not on the results of empirical investigations, but rather on the authors' agreed collective opinions. This is a relatively new technique of nonparametric analysis which, I suppose, will be used more frequently owing to the increasing costs of statistical studies. The method has the obvious advantages of being economical, but the disadvantage of being subject to the particular biases of its practitioners.

In Part II the authors develop their theory of the decision-making process by which objectives and instruments are chosen. The principal policy-makers are parliament, political parties, government (politically appointed officials), administration (permanent civil service and associated agencies), interest groups, foreign and international influence, and courts. The authors state: "The role of Parliaments . . . is a declining role in the decision making process . . ." (I, p.159), which they explain by the expansion of public policies (I, p.164) and "through the development of parties as disciplined and autonomous bodies. . ." (I, p.193), but this is not supported by any analysis and rests, like most of their other statements, on their collective opinions. The authors propose a law about the distribution of influence between the important policy-makers: "the influence of the Administration is an inverse function of that of the interest groups and the political parties" (I, p.236). Again, I regret that they did not attempt to analyze and illustrate the relationship, nor to explain whether the casual relationship is only from interest groups and political parties *towards* the administration or whether all three are dependent upon other factors, too.

The authors also conclude that short-term objectives take priority over long-term ones (due to the priority of the urgent), but this is later weakened by their statement that the long-term objective of economic expansion provided the chief focus of policy in France, Italy, and Norway throughout the entire period, was dominant in Germany during the first half, and rose to the first rank by the end of the period in Belgium (I, p.348). Further, they believe that there is less disagreement over objectives than over the instruments to achieve them, because instruments affect different economic and social groups. While global multipurpose instruments are preferred to the more efficient instruments because the former have a greater probability of success, the authors formulate another law that instruments are preferred "in inverse ratio to the degree of intervention that they involve" because intervention carries a psychological cost (I, p.243).

A final chapter in this part discusses time lags between the recognition of a public policy issue and the taking of decisions to deal with it. This a useful addition to the theory of economic policy, since economists generally emphasize the efficiency and time dimensions of instruments *after* the decisions have been made. The authors expect the time lag to increase because society is developing better-organized interest groups and international institutions which add a new consultative period to the decision-making process.

Part III concludes Volume I by highlighting the general characteristics of economic policies for two short-run objectives (inflation and recession) and two long-term objectives (expansion of production and improved income distribution). There are also two final chapters on international cooperation and European economic integration. This part of the book, unfortunately, makes little effort to utilize or illustrate the theories developed in Part II and, for those familiar with Maddison's account of postwar European economic growth, these chapters will add little.²

² Angus Maddison, *Economic Growth in the West*, New York 1964.

Volumes II and III contain eight country studies, each from 70 to 150 pages. While each was prepared by a different economist, there are only minor differences in description, analysis, and style. The terminology of objectives and instruments developed in Volume I is used uniformly to describe each country's economic policy between 1949 and 1961. A brief summary of the important political and economic events introduces each study, followed by a section on short-term policies and another on long-term ones. The principal objective was to present an exhaustive chronology of each policy measure taken, and for this reason these volumes will be immensely useful for further work, but timetables make painful reading. There are few similar studies, but anyone who has read, for example, Dow's analysis of postwar economic policy in Britain will be disappointed by these colorless accounts.³

There is very little correspondence between the complex power relationships which form the basis of the theory of economic policy presented in Part II of Volume I and the play-by-play description of policies actually implemented in Volumes II and III. In spite of the introduction's caveat that the method of presentation inadequately reflects the interdependencies, one cannot help but conclude that the implicit practices of the policy-practitioners confirm Tinbergen's ten-year-old description. He called them "incoherent" because the instrument changes are:

. . . more or less arbitrary . . . and if after some time they appear to have been insufficient, something more is done. Or, if the first change overshoots the mark, a change is made back in the opposite direction. . . . Measures regarding various instruments are taken separately . . . to some extent based on the belief that there is a one-to-one correspondence between targets and instruments (*op. cit.* pp. 54-55).

Tinbergen hoped that the interrelations and simultaneous considerations could in the future be considered, but these country descriptions lead one to conclude that the practice of economic policy is far removed from contemporary theory.

In sum these are not easy volumes to evaluate. The theory of economic policy presented in Volume I adds a new dimension to Tinbergen's insofar as it defines the power relationships and time lags existing prior to applying an economic instrument, but no attempts were made to measure or evaluate the efficiency of the instruments now or to tell when or how objectives were attained. Explicit models would have made the volume more useful to economists. The two volumes of country studies are clearly not designed for continuous reading, but they do provide excellent references for further studies of economic policies.

Business Fluctuations

Gold and the South African Economy—The Influence of the Goldmining Industry on Business Cycles and Economic Growth in South Africa 1886-1961. By LEO KATZEN. Cape Town: A. A. Balkema, 1964. Pp. 115. \$3.00.

Leo Katzen's book, a revised version of his M.Sc. thesis written in 1954 for the London School of Economics, examines the influence of the gold mining industry in South Africa on the country's business cycles. Since the amount of gold produced in South Africa has shown a remarkably steady climb, with little trace of cyclical fluctuations, the influence of gold mining on business cycles has obviously been stabilizing. The notable declines in gold production in the early 1920's and mid-1940's follow such exogenous influences as strikes and war, while the accelerated increases in the industry's rate of growth in the late 1930's and 1950's are the result of devaluation and windfall new discoveries of gold.

The stability of the rise of the gold mining industry in South Africa is based on the fixed dollar price for gold since 1934. The theory of gold production, in a world anchored to a fixed gold price as a "built-in stabilizer," is outlined very well by Katzen in the first two chapters (pp. 1-14) of his book. These are the two most valuable chapters of the book, since they relate recent trade-cycle theory to older studies such as Professor Frankel's classic *Capital Investment in Africa*.

The remaining four chapters (100 pages) of the book are less likely to capture the attention or confidence of the reader. His conclusion, that gold mining has been a stabilizing influence on the South African economy, but not as much (particularly in the discovery stages) as a pure theorist might in his dreams expect, is pretty obvious and unexciting.

Katzen concludes that the future of gold mining as a major sector of the South African economy seems assured for some time to come, but it should be noted that its continued expansion is not assured. The mining companies are increasingly moving into industrial activities, in recognition of the limited scope for future growth of gold output. Failing Dr. Busschau's touted medicine of an increased price for gold, it is generally expected in South Africa that a ceiling on annual gold output will be reached in about seven years at the outside. Government planners and private entrepreneurs are looking to manufacturing industry to provide the expansion which will maintain the country's rate of growth at an average of 5.5 per cent.

Katzen's book has some valuable nuggets buried in it, but one has to dig. Trade-cycle theorists may be put off by the technicalities of South African gold statistics, while those specially concerned with the gold mining industry may find the application of trade-cycle theory to their subject an unfamiliar exercise. Chapter 4, on the importance of the gold mining industry in the South African economy, goes over old ground (see, for example, Chapter 5 of Houghton's *The South African Economy*). The following chapter, on the effect of the gold mining industry on South African trade cycles, is a rather

uninspiring application of gold mining statistics to Professor Schumann's studies of the South African trade cycle.

Katzen's main contribution is a refinement of the theory of the stabilizing influence of gold production in a fixed-gold-price world. It is, of course, a special case since in no other country does gold production play as important a role in the economy as it does in South Africa.

JOHN A. MARLIN

Washington, D. C.

Money, Credit, and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

Inflation and the Theory of Money. By R. J. BALL. Chicago: Aldine Publishing Co., 1964. Pp. 313. \$7.50.

This is a selective survey of inflation theories, intended for graduate students. Much of the book develops the author's own theory, a synthesis of demand-pull and wage-push views.

The first four chapters compare simple Keynesian and quantity theories. Two long chapters then analyze the determination of wages under unions and the pricing policies of modern business. Another two chapters develop the connection between expenditures and the demand to hold money, following the conventional theory of asset demand. A final two chapters discuss the inflationary process and the problems of preventing inflation. For students in a hurry (and who isn't?), Chapters 6, 7, and 10 present the author's theory and can be read separately.

R. J. Ball wants to unify the confusing diversity of inflation theories, and for his own contribution he purposely combines wage push and demand pull, elsewhere usually treated as alternative explanations. The combination is achieved by making wages and aggregate expenditures a function of the same variable—expected profits. A rise in expected profits raises aggregate expenditures through an expansion of investment and a reduction of business money holdings (which raises monetary velocity). Expected profits depend in part on projections of current levels of activity and unemployment. A rise in expenditures and output, therefore, raises expected profits further. The upward movement does not continue without limit: when all idle money balances have been activated or interest rates rise fast enough, the expansion stops unless the money supply increases. The model takes the quantity of money supplied as exogenous and constant.

Wage costs are brought in on the argument that they determine prices in the short run. Corporations set prices, not to clear the market, but to maintain a "satisfactory" long-run growth. Management ignores short-run changes in demand but not in costs, of which wages are the key item. In the unionized sector, bargaining determines wages. Ball portrays unions as pushing relentlessly for higher and higher money wages, but tempering their demands when unemployment increases. This relates wages to expected profits, since the latter depend in part on current unemployment. Employers' resistance to union wage

demands also depends on expected profits. Union wage gains set the pattern for nonunion industries through a mysterious "transfer mechanism" which Ball borrows from the literature on labor markets but does not clarify.

His model specifies, given certain parameters and a constant money stock, a particular rate of change in prices. Even if profits are not expected to change, wages and prices still rise because of union pressures. If profits are expected to increase, aggregate demand expands, and wages (and prices) rise faster. The rate is not arbitrary: A higher rate is not possible, because expected profits would then rise less rapidly or be reduced, thus restraining the rise in wages. A lower rate is not possible, because the expansion in aggregate expenditures would then deplete inventories and raise expected profits, thus allowing wages and prices to rise faster. While an increasing money supply could keep the inflation going forever, a constant supply eventually stops it. When the rise in velocity tapers off, aggregate demand falls and expected profits decline, which increases unemployment and restrains wages. Expected profits then fall farther, despite the slower rise in wages. Autonomous investment acts as a floor to this downward spiral. The model seems to imply cycles rather than irreversible upward movements. Expected profits play a role here similar to that of inventory investment in accelerator theories of the business cycle.

What is new in Ball's model? Although consistent with much recent writing, it goes further and makes the pace of inflation depend explicitly on both wage bargaining and aggregate demand.

What does the model help explain? I believe it has quite limited applicability. It describes a velocity inflation, as might occur during an investment boom like 1955-56. The synthesis of cost and demand factors serves no purpose unless the rise in prices during such a boom is significantly affected by the rise in wages. I see no evidence of this and much to dispute it. Moreover, most inflations (including the creeping variety of current interest) do not depend on increasing velocity. Most reflect excessive growth in the money stock. A common view is that the monetary authorities, in order to keep unemployment from rising, reluctantly create enough money to underwrite wage bargains that exceed gains in labor productivity. Whether that view is correct or not, profit expectations do not play a central part. When expenditures rise more rapidly than velocity does, the crucial question is how and why the money supply increases, which Ball's theory does not deal with.

Ball applies his theory to a period like the 1950's in this country and Britain, when velocity did rise considerably. But the rise in velocity over the decade can be attributed initially to a belated adjustment to wartime increases in the money stock and then to the upward trend in interest rates and to related financial developments, and only in certain years to a rise in profit expectations. Union wage gains may have affected the timing of those price movements but not the over-all increase. To conclude, as Ball does, that the rise in velocity during the 1950's reflected a rise in expected profits implies, contrary to fact, that velocity would fall to its original level when expected profits returned to normal. Such expectations help explain short-run fluctuations in velocity but not the long-run movements. Substituting interest rates for expected profits in the model does not preserve the synthesis, because the two variables

do not always move in unison and because wage increases are not closely related to interest rates.

Although of limited empirical applicability, the theory in Chapters 6, 7, and 10 can still be recommended to graduate students (and their teachers). Ball gives a useful discussion of the many problems of devising a theory of inflation.

PHILLIP CAGAN

*National Bureau of
Economic Research*

The Financial Sector and Economic Development—the Mexican Case. By ROBERT L. BENNETT. Baltimore: The Johns Hopkins Press, 1965. Pp. viii, 210. \$6.95.

It is Robert L. Bennett's thesis that Mexican financial institutions and policies have played a strategic permissive role in the country's recent development. While he does recognize the important entrepreneurial activities of some of these institutions (the Nacional Financiera, for example), Bennett has preferred to analyze the ways in which policy has been used to prevent financial bottlenecks from spoiling the plans of businessmen and government officials who have been the primary undertakers of innovative activity.

It is probably impossible actually to demonstrate that financial policy has been crucial to recent Mexican development. Nevertheless, Bennett does present an interesting case. He first builds a model of an economy in transition from a traditional state, in which per capita income is constant, to a state in which per capita income is growing. Arguing that the Mexican case resembles his model in all essential respects, Bennett proceeds to evaluate the role of Mexican financial institutions and financial policies in terms of the model.

The traditional economy is dominated by traditional finance. Net and replacement investment are derived mainly from internal funds of the firm and from short-term bank loans. Poorly organized capital and money markets create severe difficulties for those who wish to raise funds outside the highly personalized sources of traditional finance. But a transitional economy requires innovative investment. Such investment is made by entrepreneurial elements outside the bailiwick of traditional business and traditional finance.

Most economists will recall the capitalist-banker, whose role it is in the Schumpeterian system to provide entrepreneurs with innovative, albeit inflationary, capital. In Bennett's traditional economy, there are few such bankers. Hence the problem for planners becomes one of innovational finance—the creation of institutions which can wrench financial capital from the traditional sector and put it in the hands of innovating entrepreneurs, preferably in a way which avoids inflation.

Apart from using the fisc, government planners might both manipulate existing financial institutions and create new ones to compete with or complement existing ones. Existing institutions can be forced to invest in innovative projects of both government and private business. Government banks can be created to service new industries. The trick is to use the system of regulation

and new banks in a way which avoids inflationary finance and which does not weaken existing traditional banking institutions. The latter's short-term liabilities militate against the heavy use of their assets for long-term innovative investment, and they tend to specialize in liabilities preferred by traditional surplus-spending units.

Government banks can only partially compete with traditional banking and financial institutions in providing acceptable liabilities to the saving public, mainly because the assets of government financial institutions tend to specialize in long-term securities from innovative borrowers. This means that short of additional governmental funds raised from taxes, government financial intermediaries must raise noninflationary finance from other intermediaries. This can be done in three ways. First, from government capital grants or loans financed by sales of government securities to private financial intermediaries who correspondingly reduce private loans. Second, from foreign borrowing. Third, from sales, forced or voluntary, of government or intermediary liabilities to private intermediaries.

So managed, such a financial system would come to take on the following characteristics: First, a system of private financial intermediaries whose liabilities, relative to the governmental intermediaries, are specialized to business and individuals and whose assets are relatively specialized to government securities and liabilities of other intermediaries. Within its holdings of private obligations, the private intermediaries would specialize in short-term, as opposed to long-term, loans and investments. Second, government financial intermediaries would have liabilities heavily weighted by borrowings from other intermediaries and by foreign debts. Their assets would emphasize long-term loans and investments and might even predominate over the private financial intermediaries in loans and investments made in the private business sector.

Basically, this is the story Bennett tells for Mexico. By the early 1940's, Mexican financial legislation had evolved an elaborate system of controls and governmental intermediaries. This system was manipulated in subsequent years for the purpose of channeling finance into the points of the economy which the government sought to promote—presumably the innovative sector—and also for the purpose of preventing such promotion from resulting in excessive inflation. The success of this financial program may be seen in the progressive mildness of inflation in Mexico from 1945 to 1960 and in the sustained rapid rate of growth in per capita real income. This experience may be sharply contrasted with the high degree of inflation both in Mexico before the system of controls and institutions were perfected and in other Latin American countries.

This generally favorable picture of Mexican growth was associated with changes in the characteristics of financial institutions which might be expected on the basis of Bennett's model. Between 1944 and 1959 private intermediaries increased their holdings of government securities from 8 per cent of the holdings of such securities by the whole financial sector to 55 per cent. In 1959, private intermediaries accounted for only 41 per cent of financial-sector loans (and 38 per cent of long-term loans and investments) to private business and individuals, as opposed to 60 (and 55) per cent in 1944. Private in-

intermediaries in 1959 held 80 per cent of the total financial system's holdings of intermediary liabilities, whereas in 1944 they held 62 per cent. In the meantime, of course, the movement of the assets and liabilities of government intermediaries moved in exactly the opposite direction. In addition, government financial institutions contracted for all the foreign debt held by the financial system (mainly through the Nacional Financiera). While all this was happening, the government and private financial intermediaries maintained roughly the same size relationship to each other in terms of assets of the whole financial system.

This basic statistical story is elaborated in considerable detail in Chapters 3 and 4 and in a long appendix. Bennett is to be congratulated for his ingenuity and doggedness in telling a complex story. His results certainly do conform to the expectations of his model in many ways. But Bennett's contribution goes beyond Mexico's experience. He has blended the insights of Gurley and Shaw with the Schumpeterian theory of growth, whilst applying the mix to the planning experience of one country. In the process, he has supplied a framework for analyzing the place and task of financial planning for other countries in similar circumstances.

BARRY N. SIEGEL

University of Oregon

Monetary Equilibrium and Economic Development—with Special Reference to the Experience of Greece, 1950-1963. By XENOPHON ZOLOTAS. Princeton: Princeton University Press, 1965. Pp. xi, 223. \$6.00.

This book is divided into two tenuously connected parts, one noticeably longer than the other. In the first part (22 pages), Xenophon Zolotas presents his hypothesis that relative price stability and growth are not mutually exclusive but complementary development policies. In the second part (201 pages), he describes and analyzes the problems and progress of the Greek economy during the period 1950-63. Attempting to show (1) that what has been successful in Greek economic development is due to the strong commitment of the Greek monetary and fiscal authorities to the above-mentioned thesis, and in addition (2) that whatever structural weaknesses remain in the Greek economy are due to *other* factors (especially quantitative and qualitative deficiencies in human capital), Zolotas uses his case study to support his general hypothesis.

In Part I, inflation, as a means of promoting growth, is rejected on the grounds that the rationale often used to defend it—the “income distribution effect”—is not a realistic possibility because the wage-earning class will not tolerate a reduction in their standard of living that is already at or near the subsistence level. Even if income could be redistributed through inflation, it will still be unlikely that expenditures would be shifted from consumption to investment because the profit-earning class more than likely would succumb to the lures of luxury-type consumption goods. On the other hand, price stability is not enforceable unless living standards are rising through growth. Therefore, only by steering a course between the Scylla of inflation, on one side, and

the Charybdis of stagnation, on the other side, is either growth or relative price stability possible.

Although he warns us that the size of the passage will depend on general confidence, on the extent to which money illusion prevails, and on other particular circumstances, the author gives us neither analytical devices nor any suggestions as to how to employ quantitative analysis that might help us navigate this narrow and treacherous passage. This description of what the economist in the position of monetary authority must be like is, indeed, more that of an artist with sensitivity and experience than that of an a scientist with his bag of analytical tools and laboratory devices.

In refuting the proposition that price stability and long-run growth are separate alternatives, Zolotas seems to mistakenly imply that not only extreme, but also moderate, monetarists and structuralists argue that they *are* alternatives. Furthermore, inasmuch as the author admits that the historical situation may require variations in emphasis (i.e., inflation-riddled countries need to emphasize price stability, while low-growth countries need to emphasize growth), it would seem that Zolotas' position is not so different as he would have his readers believe.

From this general discussion of his thesis Zolotas moves on to the case of Greece. It may hardly be necessary to point out that, even if the reader should agree with Zolotas' contention that the Greek case does support his thesis, the general thesis cannot be proved valid on the basis of a sample of one. Since Zolotas has been the Governor of the Bank of Greece for the greater part of the period under consideration, his survey of Greek monetary problems and policies within the context of development is most authoritative, but hardly most objective.

Although his defenses of the monetary and fiscal policies which Greece has followed generally since 1950, and wholeheartedly since 1956, are most convincing, they do not entirely remove the suspicion that Greece might have been able to attain a similar growth rate with either somewhat more conservative or somewhat less conservative policies. Had he compared Greece's successful policies of the postwar period with the dismal failures of the prewar period, he might have made his case even stronger.

The Zolotas defense of Greek credit policy in the postwar period is much less convincing. Greek monetary authorities have practiced a discriminatory credit policy which they justify on the basis of an assumed divergence of social productivity from private profitability. No one familiar with the Greek economy will be likely to doubt that there is such a divergence, but similarly no one familiar with the formidable difficulties of quantifying the extent of divergence from sector to sector will be likely to believe that the Greek Currency Committee could have been very accurate in its intuitive judgments about the magnitude and direction of the divergences. Little evidence can be found to show that the discrimination as practiced by the Greek monetary authorities has been successful. Despite the obvious limitations in the power of credit policy, one cannot help but wonder whether *some* of the structural weaknesses which continue to plague the Greek economy (as Zolotas repeatedly points

out) might not have been due to a less than optimal credit policy established by the monetary authorities.

In responding to the charge that the Greek monetary authorities have been too restrictive, Zolotas points out that supply of credit has always been greater than demand. Therefore, he argues, the real obstacle to further growth must lie elsewhere—namely, in the insufficient quantity and quality of Greek entrepreneurs and managers. Skilled entrepreneurs are scarce in Greece as in many other less developed countries. Nevertheless, is it not possible that Zolotas is using this argument to decoy us from what may be a more fundamental explanation for the excess of credit supply over credit demand, namely, that the interest rate is too high? It is the latter hypothesis, not the former, that would seem to be most consistent with the widely accepted view that the Greek banking industry is oligopolistic.

In any case the value of the second part of the book should be judged not only by the degree to which it supports the author's thesis, but also by the quality of the analysis which the author brings to the problems and policies in Greece's postwar economic growth. It is in this latter respect that the book is most valuable, especially considering the paucity of serious studies of Greek economic problems and performance. With the exception of tariff and trade policy which unfortunately is not dealt with in this book, Zolotas' presentation of Greek development policies and problems is both complete and concise. It contains much information which is not readily accessible elsewhere.

University of Southern California

The Independence of the Federal Reserve System. By A. JEROME CLIFFORD. Philadelphia: University of Pennsylvania Press, 1965. Pp. 435. \$8.50.

The issue of Federal Reserve independence has received considerable attention over the years, officially from Congress and the Federal Reserve and privately from reflective policy makers such as Glass, Warburg, Willis, and Eccles. A. Jerome Clifford's book selectively reports the development of this official record.

The book begins with a discussion about the fears that the authors of the Federal Reserve Act had that the Federal Reserve might be dominated by politicians, if not by private bankers, and of the checks and balances that were devised to limit concentrations of authority within the System. It then goes on to describe the ensuing power struggles that were necessary to get around the Act's ambiguities in assigning operational objectives and implements, and decision-making authority. The author concludes with an assessment of the prospect for continued Federal Reserve independence. It is not possible to challenge the truth of his statement that the Federal Reserve can remain independent in the exercise of its powers provided Congress wants it that way, a choice that will depend on how well the Federal Reserve satisfies objectives and how clearly it explains its actions.

Though the book presents an often interesting chronology of the public re-

cord on the issue of independence, it probably does not make a very significant contribution. Sadly lacking is any reference to the rich historical experience of other countries with respect to relationships between the central bank and the government or the private banking system. Also there is no attempt to utilize numerical data in getting at the question of whether the independence of the central bank makes any real difference. And there was scant attention paid to the evaluation of the issue of Federal Reserve independence by economists or historians who did not have official status, e.g. Laughlin, Harris, Hardy, and most recently Friedman.

The narrative line of the book goes about as follows: Congress passed the Federal Reserve Act in 1913, and it has frequently altered this indenture under which the central bank operates. The Act gave the President authority to appoint Federal Reserve Board members. The Board, though frequently challenged by Reserve Banks through the 1920's, developed into the key power center within the system. Its renaming as the Board of Governors in the 1930's attached the traditional appellation of central bankers where the power actually was rather than, as before, with the heads of the Reserve Banks. The Board, however, is forced to share responsibility for monetary policy with five Reserve Bank Presidents, who along with the seven-member Board, form the Federal Open Market Committee. Nevertheless when the chips are down, the Board reigns supreme. Reserve banks are formally given authority to fix discount rates, but this power is subject to the Board's review and determination, which has been interpreted to grant the Board authority to fix rates. Reserve Bank directors formally elect the top Reserve Bank executives, but the Board retains the authority to approve or to remove them. In fact the Board's authority probably extends to every possible Reserve Bank activity through its authority to audit Reserve Bank operations. The emergence of the Board as the power center of the System has tended to increase the probable dominance of public over private interests in the operations of the Federal Reserve despite the remaining vestiges of the founders' hoped-for financial democracy. Clifford's book reminds us that the existing reasonably well-defined relationship between the Reserve Banks and the Board on the one hand and the Reserve Banks and the member banks on the other was once a very controversial issue.

By all odds the most significant power struggles historically have pitted the Federal Reserve against the Treasury, and Clifford supplies a very interesting account of them. Referring to this intragovernmental relationship, it is something of a paradox to the reviewer that an independent Federal Reserve is a creature of government designed to protect the government against its own propensity to spend excessively; yet the Federal Reserve actually has facilitated inflationary government spending during both World Wars; and these periods have been virtually the only periods during Federal Reserve existence when there was any significant inflationary impact from government fiscal actions. Clifford quite effectively analyzes the complex maze of governmental decision-making in the monetary field, returning repeatedly to the fact that the independence of the Federal Reserve is derived from Congress. Con-

gress created it, added to its powers during the 1930's, and helped free it from self-imposed Treasury domination after both World Wars. In part its independence stems from the willingness, if not the necessity, of Congress to entrust it with the detailed decision-making that goes into formulating and implementing monetary policy. Congress does require the Federal Reserve to account publicly for its actions and the reasons for taking them; and it regularly demands a detailed defense from Reserve spokesmen. But the central bank undoubtedly enjoys a large measure of freedom with respect to specific policy actions because of the wall of jargon and secrecy with which it has been permitted to respond to often-uncomprehending Congressmen. The final important source of independence is attributed to a Congressional grant of budgetary freedom to the Federal Reserve that permits it to keep its earnings separate from the Treasury general fund and not to have account to the Treasury for its expenses. Congressman Patman and Senator Douglas notwithstanding, the Federal Reserve may have been able to preserve its financial independence in some part, not only by policies that leaned with Capitol hill winds but by a policy of judicious operational expenditures.

WILLIAM G. DEWALD

Ohio State University

The Federal Reserve and the American Dollar—Problems and Policies 1946-1964. By JAMES L. KNIPE. Chapel Hill: University of North Carolina Press, 1965. Pp. xiv, 321. \$8.00.

James Knipe, currently an investment counselor, served as consultant to the Federal Reserve Board from 1959 to 1963. His book purports to be an account of the Federal Reserve System from its inception in 1913 to the present, with major emphasis on monetary policy during five postwar cycles.

Knipe begins with an analysis of the organizational structure of the Federal Reserve, makes a brief, elementary survey of how the stock of money is determined, and then turns to the operation and the goals of monetary policy. Unfortunately, the reader will not find an intellectually satisfying account of either the goals of monetary policy or the routes by which policy operates. The quality of the book can be conveyed by the following statement: "It is certainly possible over the course of the coming years, that statistical analysis may reveal more of an impact on ultimate economic objectives from a differently defined Money Supply, one which includes Time Deposits. . . . Until that time, the transmission of the original policy impulse can, perhaps, be thought of as an *influence*. A stronger word or phrase would seem to be unrealistic" (p. 31). Nevertheless, Knipe believes "The Federal Reserve holds in its hands the power to make sweeping economic and sociological changes in the nation, at least in the short run" (p. 34). The reader is not told what changes Knipe has in mind. Or again, he writes, "It is impossible, even in retrospect, to evaluate the usefulness of any monetary tool, general or selective. One's common sense though, leads to the conclusion that consumer credit control,

interrupted, criticized and attacked as it was, could scarcely have been very effective, except occasionally, during the 1946-48 period" (p. 57). In this manner, throughout the book, assertion replaces intellectual analysis.

Nor does the book provide an intellectually satisfactory account of the goals of monetary policy. Missing is any awareness of trade-off ratios between goals such as full employment, on the one hand, and price level stability, on the other. What percentage of unemployment is compatible with price stability? What percentage of rise in prices is associated with a given percentage of reduction in employment? Can these trade-off ratios be influenced by monetary policy? He makes no attempt to answer these questions, nor is any mention made of the important empirical work which has been done to determine these trade-off ratios.

Knipe does believe that the Fed should try to restrain the excessive degree of inflation which is being foisted on the economy by powerful economic blocs. (He does not mention any limitation that price indices may have in measuring prices.) He is opposed to the view that the Federal Reserve's main goal should be full employment without regard to inflation and the burden of the debt—a view, which, according to him, is increasingly prevalent, and whose proponents everywhere are "busily engaged in creating a brand new mythology of their own" (p. 33). The reader is not told who these proponents are.

He is on somewhat firmer grounds when he deals with the problems of the internal organization of the Fed. He is for competent, well-publicized research by the staff of the Board of Governors. He discusses the pros and cons, without taking sides, of whether the term of office of the Governor of the Board should be made coterminous with that of the President; he does the same with the question of whether the commercial banks should hold stock in the Fed. In Appendix C on the "Discount Rate," he comes out against a discretionary rate and for a discount rate automatically linked to market rates. Appendix B on "Bills Only" is a pastiche of questions from Congressional Reports highlighting the opposition of the New York Bank to the Board's commitment to bills only. Although Knipe gives no economic appraisal of the controversy, he is against a permanent commitment to any specific policy, and urges the System to issue a White Paper on bills only with a view to silencing critics outside the System.

Perhaps it is unfair to expect a nonacademic economist to keep in touch with an ever-growing body of professional literature. It is only fair, however, to say that Knipe's attitude towards the academic profession must be considered parochial. He writes of Keynes, "At least in universities and among members of the economic profession, he has triumphed so completely that opposition is practically invisible. To conservative thinkers everywhere, on the other hand, his name stands as a symbol for all they believe to be wrong with the postwar world" (p. 42). One can only hope that Knipe's attitudes towards the academic profession are not typically those of investment counselors.

Public Finance; Fiscal Policy

Measuring Benefits of Government Investments. Papers Presented at a Conference of Experts Held Nov. 7-9, 1963. Edited by ROBERT DORFMAN. Washington: The Brookings Institution, 1965. Pp. viii, 429. \$6.00.

This is an important book that merits careful reading, not only by economists interested in the resources field, but by others concerned with the intransigent problems of assessing the allocation of resources in areas wholly or partially divorced from the market mechanism.

The book is made up of seven essays, with critical comments, presented at a conference sponsored by The Brookings Institution in November, 1963. The purpose of the meeting was to bring the tools of microeconomic analysis to bear on a number of troublesome areas of government expenditure in which the identification and valuation of costs and benefits are beset by the familiar problems of interdependent production functions, nonpriced outputs, scale economies, etc. The full potential of benefit-cost analysis in areas other than water resources remains to be explored. It is, of course, no more than a technique for simulating the results to be expected from the competitive model under a full employment assumption, and is subject to the same limitations. But used with appropriate care, it can improve significantly the understanding of alternatives available to policy-makers and their relative economic merits. With all its problems, benefit-cost techniques have already produced much more satisfactory decisions in the development of water supplies and even in the incredibly complex maze of defense expenditures.

Seven areas of application are covered: government research and development (Scherer); outdoor recreation (Mack-Myers); prevention of high-school dropouts (Weisbrod); civil aviation (Fromm); urban highways (Mohring); urban renewal (Rottenberg); and syphilis control (Klarman). The fields selected for analysis are not trivial; each covers an important area of government investment where proper allocation assumes real significance to society. Since choices are already being made in these areas, a hard crust of noneconomic criteria for decision-making has grown up in each—some of it useful, but much of it steeped in mythology.

With some minor exceptions, the papers follow the same general format: a listing of the beneficiaries and cost bearers involved in the particular program; an evaluation of impacts on these groups of alternative types of investment in the area concerned; an attempt to quantify both benefits and costs, in total and for particular groups; and an evaluation of the potential usefulness of the procedure.

There is an equally strong similarity in the results that emerge from the seven papers. The first two steps, involving identification and qualitative analysis of impacts—actual and potential—on various groups, come off very well in each case. The critical problem is, of course, the extent to which benefits and costs can be estimated quantitatively to a degree sufficient to sharpen the decision-making process. There are really two elements involved. Are the estimates themselves sufficiently accurate, at least in a probabilistic sense, to pro-

vide a basis for evaluation of alternative programs? Is the range of benefits for which such evaluations can be made large enough relative to total benefits so that the tail is not wagging the dog? There is, after all, more than casual merit in the typical bureaucratic position that a high degree of precision in benefit-cost analysis involving perhaps 10 per cent of the total program is not very helpful and can be dangerously misleading if given undue weight in the planning of an investment program. These questions remain open after all the papers are read.

This is, of course, to be expected. No claim is made by any of the seven authors that benefit-cost analysis can provide final answers to government decision-making, and all recognize that the present state of the art is hardly satisfactory even for the more limited objective of identifying and quantifying all potentially measurable costs and benefits. The essays are intended to advance techniques rather than to provide methods of analysis of immediate and general applicability.

An assessment of the book as a whole is difficult, since it depends on one's attitude toward complete coverage of a minor issue vis-à-vis incomplete but imaginative treatment of an impossible one. On the one hand, it is refreshing to see conceptually sound, hard-bitten appraisals of the technical requirements of benefit-cost analysis as applied to the areas in question. If nothing else, the exercises justify themselves by providing seven examples of proper definition of benefits and costs—an achievement much less common than one might expect. On the other hand, it is hard to avoid the conclusion that all of the essays have failed in the sense that the demolition of incorrect concepts and techniques of measurement is not matched by even a good start toward evaluation procedures that are analytically sound and also operational.

Scherer's excellent statement of the problems of evaluating research and development, for example, is followed by a suggested technique that falls almost in the category of "tinker-toy" economics—ingenious but not a particularly useful guide to serious empirical work. Burton Weisbrod's paper on the school dropout provides an elegant analytical framework for empirical study, but appears to force more out of limited data on a single case study than should have been attempted, even before a professional audience. Good work in this field is so rare that even the shabbiest of empirical results are likely to receive public fanfare far beyond the intention of the conscientious author. In brief, all of the papers deserve an A for effort in delineating analytically the problems to be resolved. The fact that none provides, even for limited cases, a pro forma for general application is not an indictment of the author, but rather a testament to some glaring gaps in our factual and statistical information and general neglect of an important area of research.

There are some questionable spots in the book, as one would expect in experimental work of this sort. In several of the papers there was a somewhat surprising tendency to create uniqueness where none really need exist. Scherer's paper, for example, emphasizes the necessity of considering trade-offs relating to time—that is, the possibility of achieving earlier completion of a research and development project by incurring higher costs and the important

limitations on the technological substitutability involved. In his hands, the concept is handled skillfully indeed with respect to research and development, but surely the same problem is involved in education (or, to use the new jargon, investment in human capital) and, for that matter, in many types of sequential investment in physical capital.

A much more serious example is the analysis of the benefits from outdoor recreation in the Mack-Myers paper. There can be no quarrel with the usefulness of their analysis of the internal structure of the demand for outdoor recreation but it does not justify the conclusion that such services are therefore unique. Outdoor recreation, enjoyed in judicious moderation, doubtless contributes to economic welfare after the fact, in subjective satisfaction through subsequent recall and through delayed external effects on others of the physical and emotional well-being generated by the activity. But surely the same reasoning applies to a tasty and dietetically balanced meal, a concert by a competent symphony, and perhaps even the selection of a stylish and properly tailored suit of clothes. If one begins to chase the will-of-the-wisp of secondary and tertiary reactions to specific consumption decisions, the world of microeconomic choice becomes even more of a jungle than it need be. For purposes of benefit-cost analysis the economist is not particularly concerned with the individual components of the experience that lead a consumer to choose a particular type of outdoor recreation service over other uses of income. Rather, he is interested in the aggregated consumer response, the subsequent claim on land and water resources, and the extent to which the net contribution to economic output to be attributed to the resulting activity can be measured.

The real danger in the Mack-Myers analysis of the demand for outdoor recreation is its use as a basis for rejecting out of hand the usefulness of the price system as a guide to investment in recreation facilities. This is clearly one of the many areas in which outputs are not priced as a matter of policy rather than technical necessity. In some respects the excellent technical discussion by Mack and Myers and their interesting and potentially useful alternative to the pricing of outdoor recreation are weakened by this partial lip service to the emotional approach that regards outdoor recreation as a service somehow above the more mundane mechanisms of choice.

Several of the papers either ignore or deal only superficially with the problem of uncertainty. Perhaps this is an outgrowth of the presumed instructions to cast the papers in the framework of benefit-cost analysis, most of which is carried out in terms of conventional static microeconomic theory. Nevertheless, in several of the papers—most notably in those dealing with research and development and urban highway and renewal programs—it is not made completely clear that the degree of uncertainty and alternative methods of dealing with it may alter the whole structure of an investment program, at a point in time and sequentially.

As editor Dorfman points out in his introduction, the battle lines between theorists and practitioners were clearly drawn at the conference, and they are evident in the remarks of the commentators. Some merely confirm the fact that inertia and mythology die hard. Others reflect warranted concern with

the degree of abstraction in the papers and the potentially dangerous errors that may arise from application to situations where key assumptions cannot hold.

Sitton, commenting on Mohrer's analysis of investment in urban highways, raises one such issue that cuts across the whole volume. Where the real world poses government investors with plural aims, can we assume safely that a value system based on segmental optimization of individual choices provides correct answers? Ferguson, dealing with the same paper, raises another intriguing problem that is relevant to most of the other essays. Is it not possible that application of user costs, given present uncertainties, may lead to self-perpetuating overinvestment in some fields, particularly where practical politics make it difficult to prevent full utilization of all revenues in the segment from which they are derived? Further, where government investment alters the structure of society it can, to a considerable extent, "create its own demand."

One word of caution might be introduced in conclusion. This reviewer would align himself firmly with those who argue that economic analysis—as one highly useful and economical method of isolating and evaluating choices—should be pushed much further in the allocation of resources in government investment of the types explored in this volume. But there must be concern lest the enthusiasm for benefit-cost analysis warp the very research process itself. There may well be a tendency, with increasing insistence on justification of government programs in benefit-cost terms, to discriminate against more basic types of research—precisely those where government participation is most productive—and even to alter, not always desirably, priorities for mission-oriented research to favor projects that promise readily quantifiable results. The same argument could be extended to the programming of projects in other fields covered by the authors of the seven papers and might be even more applicable in the Bureau of the Budget's final review of possible departmental trade-offs. Benefit-cost must be regarded as a tool to assist in decision-making, not a rigid framework to which the planning itself should be directed.

JAMES A. CRUTCHFIELD

University of Washington

Federal Lending and Economic Stability. By GEORGE F. BREAK. Washington: The Brookings Institution, 1965. Pp. ix, 185. \$5.75.

This study ably develops data and analytical tools needed for appraisal of the past influence of federal credit programs on economic stability and for interpretation of their future potential as an instrument of economic stabilization policy. The book, which is well written and readable, is a basic source for those interested in government credit programs. Because of the careful way in which Professor Break interprets the effects of loan expenditures, his approach may be a useful reference point in connection with discussion of the effects of other stabilization policies. The study reaches interesting conclusions on particular questions, but does not offer any general prescription as to the use to be made of government lending programs.

The central substantive chapter (2) deals with the economic effects of federal lending (effects upon total demand rather than upon resource allocation). In this, the author considers six distinguishing characteristics of such loan programs and derives from his discussion results applicable to six policy questions: (1) a suggested system for improved budget reporting of loan programs; and the conclusions that (2) theoretical analysis does not suffice to support the common belief that loans affect total demand less than other government expenditures; (3) sales of loans by the government during periods of monetary ease and excess unemployment cannot be recommended on stabilization grounds; (4) loan programs are not well suited to be automatic stabilizers; (5) government loan programs designed to fill a private credit gap might desirably be set up as independent agencies financed by sales of their own securities, and (6) terms on government loans should not be based upon the government's borrowing costs but rather upon a system based upon welfare aspects of federal lending (pp. 39-46).

An interesting feature of this chapter is its use of the concept of the "fiscal offset" to net loan expenditures (pp. 19-27). It is pointed out that: "Like any other kind of federal expenditures, loan disbursements can be financed in four ways: by the creation of new money, by borrowing from private investors, by reducing federal expenditures for other purposes, or by increasing taxes" (p. 19). The interpretation, then, involves an effort to identify in particular cases the "fiscal offset" that "financed" a change in loan expenditures. Was a net increase in loan disbursements "financed," in effect, by increasing government borrowing over what it otherwise would have been, by holding other government expenditures below what they otherwise would have been, etc. This is a subtle and demanding interpretive framework, one that does not lead to easy generalization. It involves an effort to answer with reference to each historical situation the question: "If loan expenditures had been different from what they were, what, realistically, would have been the offsetting transaction?" Extended to fiscal policy in general, this approach would involve analysis in terms of alternative packages of net government surplus plus defined financing transactions.

Within this framework, the author's judgment is that during most of the period 1947-62 federal loan disbursements were marginally "financed" by restraint in other expenditures and in tax reductions rather than—the association that might offhand have seemed most plausible—by additional government borrowing. Given that the central constraint on fiscal policy has been concern over the government deficit, this interpretation is not unreasonable. It leads to the observation: "To argue that loan disbursements have frequently been made at the expense of other types of federal spending is to raise the intriguing possibility that expanding loan programs have actually exerted a net deflationary impact on aggregate private demand" (p. 81).

In analysis of the effect upon total demand of "autonomous" changes in investment or government expenditures, an accounting for the financing of the expenditures and its effects has not always been made. Earlier versions of neo-Keynesian theory seemed to justify this on the basis that financing constraints are generally unimportant. Since such a presumption now seems less supporta-

ble, the technique used here by Break may come to be more widely applied, and developed to permit more effective generalization of findings.

A chapter (3) on the characteristic behavior of net expenditures of lending programs interprets this in terms of program life-cycle and of relation to business cycles, including a chronological review of the behavior of lending programs in relation to economic fluctuations. If the test of being adjudged anti-cyclical in a recession is that major loan programs must show net outlays larger than during the preceding business-cycle expansion, the test is passed in only one of the three recessions covered (pp. 78-79). Within the terms of reference of this study, such a test is to be modified on the basis of an estimate of the "fiscal offsets" to changes in loan programs. The author offers a set of estimates of "most probable fiscal offset to federal loans" in each year (p. 80), but of course is not able to tie this information into any quantitative package.

The study also considers the characteristic behavior patterns of different classes of loan programs in relation to their potentialities as a stabilizing device (Chap. 4) and concludes that some programs would be susceptible to use for stabilization purposes and could generate sizeable swings in net loan disbursements. An appendix gives information on the major lending programs.

J. M. CULBERTSON

University of Wisconsin

The Tax on Value Added. By CLARA K. SULLIVAN. New York: Columbia University Press, 1965. Pp. xii, 340. \$10.00.

Dr. Sullivan had an opportunity to write an extremely valuable book on her chosen subject. By and large, value-added taxation has not received much attention from public finance specialists in their treatises or textbooks. At the same time there have recently been important practical developments, with the near-introduction of this tax in Japan and the success story of its operation in France.

Unfortunately, it cannot be said that the author has made the most of her great opportunities, as there are a number of disappointing features of the book. First, it is rather long-winded and at times tedious. Accurate footnotes and references are of great importance, but, to give one example only, it is surely straining the patience of readers to the limit to refer us (p. 221) to a U.S. Treasury source for the proposition that high tax rates create an incentive to evasion. Secondly, the order of treatment could have been better. We start with a 50-page introduction to the concept, switch over to 100 pages on the Japanese and French systems, revert to another 60 pages or so of theory, turn to administration, and finally back to theory again. Some improvement on this seesaw system could surely have been made.

Thirdly, there is a lack of decisiveness in dealing with some of the theoretical issues. These are certainly complicated and no one would dream of denying the need for a cool and balanced approach. But this is a different thing from setting out thesis and antithesis at length, without ever reaching a synthesis. Nailing one's colors to the fence is not always the most profitable of

occupations. Fourthly, despite the author's assurance in the preface that the original Ph.D. dissertation has been revised up to date, there is not much discussion of the recent material in this field, e.g., the Neumark Report of 1963 and the developments in the E.E.C., or the arguments surrounding the Richardson Report (of March 1964) in the United Kingdom.

Obviously, some of these faults are due to the transformation of a Ph.D. thesis into book form, with insufficient editing, pruning, and reshaping. But one suspects that there were also some unresolved difficulties in the presentation of the original thesis. One is that the attempt to combine history of thought with modern analysis was really a form of self-crucifixion. Another is that the author wanders somewhat unhappily from the realm of absolute to that of differential incidence, without ever settling down in either. It surely makes a good deal of difference whether one is dealing with the case for value-added taxation versus sales taxation, value-added taxation versus profits taxation (the genesis of the recent U.K. interest in the subject), or value-added taxation together with extra spending or with higher budget surpluses.

Despite these reservations, one must recognise and pay tribute to the very solid and very real merits of the book. It is certainly comprehensive—at least up to the end of the 1950's; it is carefully and clearly written; and the last thing that anyone could say about it is that it is unscholarly. As a meticulous history of the literature of many countries on this subject, it will unquestionably be definitive. What cannot be said is that it is a simple guide for students or an incisive analysis for theorists.

A. R. PREST

University of Manchester

Nigerian Public Finance. By P. N. C. OKIGBO. Evanston: Northwestern University Press, 1965. Pp. xiii, 245. \$6.50.

In the last decade Nigeria has not only attained a position of prestige and leadership in African affairs, but also has become a center of attention for students of economic development. With the largest population of any African country, with substantial resources, with (at least until January 1966) a relatively stable government despite the diversities of people and cultural backgrounds, Nigeria offers fruitful ground for study. Though less dynamic in its growth policies than Ghana, and lacking the contributions of the dual economy of Kenya, it had avoided the most serious problems which beset these countries.

While a number of studies of various aspects of Nigerian development have appeared, literature on public finance has been limited to Royal Commission reports, the Orewa book on taxation in the western region, and brief summaries in broader studies of African taxation. Yet government expenditure and revenue programs obviously have great significance for economic growth. This volume by Dr. P. N. C. Okigbo, one of Nigeria's most distinguished economists, fills the gap very effectively. The work is an outgrowth of material prepared by Dr. Okigbo for his work on the Kenya Fiscal Commission of 1962. A thorough review of the development of the public finances of Nigeria serves as

the background for the analysis of the present structure, at federal, regional, and local levels.

Public finance in Nigeria has been greatly influenced by the federal nature of the governmental structure, and intergovernmental fiscal relations have been the center of attention of various Royal Commission and other studies in the country. Since the regions cannot collect adequate funds to meet their expenditure needs, sharing of federally collected revenues has been imperative. Colonial emphasis on allocation of revenue on a derivation basis has given way to increasing attention to need, but conflicts among the regions on this and other issues remain.

Indirect taxation, for the most part federally administered but with revenue shared with the regions, is the major revenue source, as it must be under the circumstances. Customs are still primarily revenue-oriented, but with increased use for protection and foreign-exchange control purposes. Export duties are significant revenue sources. An excellent beginning has been made in the income tax field. Antecedents of this tax are to be found in precolonial Northern Nigeria, and these levies were continued and expanded under the indirect-rule policy and since independence. But Eastern Nigeria was the pioneer in the use of a modern income tax applying to most families, and collected in part through PAYE (withholding). All regions now use the income tax—in the East and the West the tax extends down to the lowest income levels; in the North and Lagos the lower levels are reached by a separate personal tax levy. Local taxation is still somewhat fragmentary, with property tax significant in only a few urban areas. Corporation tax is a federal prerogative.

Okigbo recognizes that indirect taxes must continue to be the primary revenue source, but stresses the need for further development of income taxation, particularly to increase the built-in stabilizing feature of the revenue system. He concludes that the country could raise substantially more revenue to aid economic development without injuring incentives through improved fiscal administration and improved tax structure, but recognizes the dangers to incentives of excessively high taxes. The book stresses the revenue side, but also reviews expenditure patterns. A major thesis of the book is that too many resources are allocated to elementary education and too few to mid-level education.

The book is highly readable; Okigbo has a facility for summarizing complex material without superficiality on the one hand or excessive detail on the other. Only a few questions can be raised. Most of the data do not extend beyond 1962. However, there has been little drastic change since that year, except for the establishment of a fourth regional government, that of the Mid-West Region, with Benin as the capital. The role of the Income Tax Management Act, federal legislation which provides the basic framework for regional income taxation, and the effectiveness of the tax holiday legislation might have received greater attention. But on the whole the book is an excellent contribution to the growing but still limited literature on public finance in tropical Africa and developing areas generally.

Macroeconomics, Fiscal Policy, and Economic Growth. By NORMAN F. KEISER. New York: John Wiley and Sons, Inc., 1964. Pp. xx, 525. \$9.75.

This book is intended "primarily for use in the Fiscal Policy half of the year course in Public Finance, although it should be easily adapted to other courses with a macro-economics and policy orientation" (Preface, p. vii). This objective separates Professor Keiser's text from numerous others planned more for semester- or year-long courses in macroeconomics, which are broader in scope and which give less coverage to fiscal policy.

The volume is divided into six parts. The four chapters of Part I cover "Goals, Conflicts, and the Role of the Federal Government." After a brief statement of the recent development of fiscal policy, Keiser introduces the fiscal policy goals of full employment, price stability, economic growth, and the balance of international payments. He presents various views of full employment from recent and contemporary economists and public figures. The possible conflicts between the various goals, especially between price stability and full employment and growth, are highlighted.

Part II includes three chapters devoted to income theory. Starting first with only consumption and investment, the multiplier and acceleration principle are developed. Next, government spending and taxation are introduced, followed by the effects of monetary and interest rate changes on the components of national income.

Fiscal policy to raise incomes and to combat inflation is spelled out in detail. Generally, at each step in this part, the new idea is presented via graphs and algebraic equations. Almost every possible change in fiscal policy is illustrated by an example in which likely numerical amounts are substituted in the algebraic equations to show the process by which change, say in taxes or government transfer payments, affects national income and its components. Unfortunately, so many examples are presented that it makes the section unnecessarily long and tedious.

"Problems and Theory of Economic Growth" is the topic of Part III. The first of this part's two chapters includes the factors making for growth, including increases in productive capacity. The Domar and Harrod growth models are presented and appraised. The other chapter compares the potential economic capacity and growth of the economy with the actual amounts, relying heavily on studies of the Council of Economic Advisers, Joint Economic Committee of the Congress, and the National Planning Association. Here, and elsewhere in the book, Keiser emphasizes the lack of sufficient demand as the major cause of excessive unemployment and inadequate growth.

In the next section, Chapter 12 traces out the effects of changes in the level and progressivity of taxes and various government expenditure programs on consumption. The following chapter covers the influence of certain tax changes on investment. Especially good is the treatment of various methods of depreciation, tax credits, and investment allowances relative to incentives to invest. Numerous examples are cited from recent U.S. and Swedish experience.

Part V, "Policy Problems in Fiscal Policy," covering seven chapters of al-

most 200 pages, is the heart of the book. The various measures of the federal budget in the United States are presented critically. The concept of the "full employment surplus" is well covered, together with examples of its size and importance over the last decade. Both the structural transformation thesis and the inadequate saving-investment thesis are presented and refuted. Keiser finds the inadequate demand and full-employment surplus ideas much more convincing.

The strengths and weaknesses of discretionary and automatic stabilizers are presented, and also the problems of forecasting and timing. Possible use of discretionary tax cuts is discussed at length. Separate chapters cover the "Monetary Aspects of Fiscal Policy," "Inflation," and the relation of the public debt to fiscal policy.

The final chapter in this part deals with possible improvements in stabilization policy, emphasizing alternative organizational arrangements for more effective policy in the executive and legislative branches of the federal government, including the Federal Reserve Board.

Part VI covers the history of fiscal policy since 1930, with one chapter dealing with the period up to 1952 and the other chapter covering 1953 to 1962.

This book is strongly oriented toward economic policy issues. Keiser identifies proponents of various viewpoints in his discussion of policies. The economic policies of the national administrations since 1930 are evaluated, with greatest attention to the postwar period. William McChesney Martin receives much attention as a proponent of economic policies which Keiser thinks are often unwise. A three-page extract (pp. 46-49) of an interchange between Martin and the late Senator Kerr from a Senate Finance Committee hearing is included, and also a three-page appendix (pp. 405-7) devoted entirely to a critical presentation of Martin's views.

References to recent and current journal articles and reports of the Council of Economic Advisers and the Joint Economic Committee give teachers and students abundant sources to develop different ideas and controversies much more fully. This is a major feature of the volume. Empirical data are generously provided, with numerous tables and graphs presenting income, employment, prices, and various measures of the federal budget. For example, quarterly GNP data in constant dollars from 1947 through the first quarter of 1963 are presented in a six-page table.

Keiser devotes very little attention to the balance of payments. He does identify the balance of payments as one of the four problems which are the major objectives of fiscal policy early in the book. For the remainder of the volume, no significant attention is given to possible uses of fiscal policy to meet the balance-of-payments form.

The text is concerned almost exclusively with the recent fiscal policy in the United States. Except for a reference to the Swedish investment reserve, the examples of fiscal policy are chosen from U.S. experience. Fiscal policy for countries with other institutional arrangements and at other stages in their economic development is not discussed.

Keiser writes as a political economist. He makes his value judgments clear; he evaluates as well as describes the fiscal and economic policies in the United

States. I felt he was unfair at one point where he describes at some length the Eisenhower administration's fiscal policy in 1953-54, emphasizing the reduction of federal purchases of almost \$15 billion but omitting on these pages (pp. 494-95) any reference to the end of the Korean War, which accounted for a large part of the decline in expenditures.

I believe the book would be much improved if the material had been covered in fewer pages. It would be further improved if the space saved were used to broaden the coverage of fiscal policy to other topics and types of economies as suggested above.

All in all, Keiser has presented an adequate text for the course for which he planned it. It offers abundant opportunities for lively discussions of tax, expenditure, debt, and monetary policies in the United States since 1930, especially if used with readings which highlight different points of view.

The Balance of Payments Statistics of the United States—A Review and Appraisal. Report of the Review Committee for Balance of Payments Statistics to the Bureau of the Budget, April 1965. Washington: Superintendent of Documents, 1965. Pp. xiii, 194. Paper, \$1.50.

In recent years so much has been written and so much has been done about the deficit in the U.S. balance of payments that it must come as a surprise to the outsider to learn that the experts have been very far from agreement as to how it should be measured. The Bureau of the Budget appointed a committee¹ to review balance-of-payments statistics in April 1963. The Committee submitted its unanimous report two years later. A subcommittee of the Joint Economic Committee, after hearing a number of witnesses, submitted its recommendations, and the Department of Commerce, together with the Budget Bureau, has recently announced its intention of implementing many of these recommendations. The most interesting recommendation—that henceforth the official measure of the deficit be given in two forms—is shortly to be put into effect. The Department of Commerce will continue to measure the imbalance in accord with the "liquidity" concept it has been using in recent years. But it will also provide an alternative measure of the imbalance employing the "official settlements" concept urged by the Bernstein Committee. With two figures of the deficit to choose from, one can only hope that the masochistic drive which seems to imbue those who have responsibility for policy in this field will not lead any of them to add the two figures in order to get a proper measure of the deficit.

Many of the Report's findings, though important, are scarcely controversial. The Committee has appraised the basic data which go into measuring the balance of payments and has found serious deficiencies—surely far more of them than most users have suspected. The accuracy of the figures even for

¹ The members of the Committee were Richard E. Caves, George Garvy, Walter E. Hoadley, Harry G. Johnson, Peter B. Kenen, Roy L. Reiersen, and Charles F. Schwartz, with Edward M. Bernstein as chairman.

merchandise exports and imports is questioned: "The procedures which generate the export and import statistics, even if perfectly administered, would still provide data that would need adjustment for which the necessary information is not now at hand" (p. 33). Valuations are suspect for both exports and imports. Data on travel expenditures are subject to doubt. The information about government transactions is far from clear-cut, especially in respect to timing. Figures on direct investments are uncertain, and those for portfolio investments are no better. And the balancing item "Errors and Omissions" has been far too large, and its changes in certain periods have been so big as to make any analysis of the forces operating on the balance of payments impossible. Moreover, this category probably contains an item which is of special importance in measuring the imbalance on the basis of the liquidity concept; but by its very nature the size of that item cannot be ascertained.

There can be no doubt about the enormous value of the Committee's work in spotlighting deficiencies in the data and in suggesting remedies. Obviously not all its suggestions for improvement will be adopted, largely because of the expense involved, but the Committee seems to have shown good judgment in making its appraisals about data being collected and recommendations for their improvement. From now on if we are going to follow their particular set of guides, we will have some reason to hope that they are adequate. The Report also recommends changes in the format of the balance-of-payments accounts which should make them more convenient to use. On these technical matters the members of the Committee have done an excellent job.

But the Report has attracted most attention because of what it had to say about the conceptual issues: how should a balance-of-payment disequilibrium be measured in the accounts? Here too the Report makes an important contribution in raising questions and sharpening issues, although it is by no means clear that the Committee has found the best solution.

If *all* the payments and *all* the receipts of a country were measured accurately, the totals of each would be identical. If an imbalance is to be detected, it is necessary to isolate those items in the record that give evidence of an imbalance, putting them "below the line." Then the difference between the payment items and the receipt items that are left above the line (the deficit--if the difference is positive) must equal the corresponding difference for the entries below the line (the means of financing or settling the deficit). The one big question is where the line ought to be drawn.

The Department of Commerce of course puts change in U.S. holdings of gold and convertible currencies and in its IMF position below the line, and recently it has also put there changes in "liquid" U.S. liabilities to foreigners. Incidentally, the Committee does well to remind us that the official concept itself has been modified from time to time. The Bernstein Committee recommends as an alternative that the below-the-line items include changes in: U.S. holdings of gold and convertible currencies, its IMF position, and foreign official monetary institutions' holdings of U.S. government bonds and notes and short-term capital (in the United States). Thus the difference between these two measures is that the liquidity concept treats every increase in foreign *private* (and official but *nonmonetary institutions'*) holdings of short-term

capital in the United States and U.S. government bonds and notes as *belonging below the line*, while the official settlements concept puts these items above the line and hence regards them not as a means of financing a deficit but instead as a receipt which reduces the deficit. With relatively few exceptions, whether on a seasonally adjusted or unadjusted basis, the official settlements concept has shown a smaller deficit over the last decade than the liquidity concept, and this difference may be expected in the future.

Obviously there must be more compelling reasons for shifting to a different concept than that it provides for a lowered measure of the deficit. Here, I suggest, the Committee has stopped short of the solution to which its logic was leading. The official settlements concept, assuming that any measure of the imbalance is to be used, is superior to the liquidity concept; but it seems to me to have its own faults. To establish this, I shall first consider very briefly the notion of a balance-of-payments disequilibrium, and then examine its measurement for a country in three different situations: (a) when the country is not a reserve-currency country; (b) when the country is the reserve-currency country performing the functions of a bank for others, and their institutions and policies allow this activity to be performed; and finally (c) when the country with whose balance of payments we are concerned serves as the reserve-currency and banker country but does so in a world which fails to act so as to allow it to function in this role. This last situation is partly the one in which we find ourselves today.

The economists' concern with a balance-of-payments disequilibrium arises because the situation is one that cannot be sustained indefinitely. If a deficit situation could last forever with both the deficit and surplus countries acquiescing, there would be no disequilibrium whatsoever, and the term "deficit" in this context would be devoid of all operational significance. Thus the figure for the deficit ought to be a measure of the pressures that prevent a particular situation from continuing indefinitely.

If we supposed that a deficit had to be completely financed by paying out gold and that all other receipts—from borrowing or anything else—were sustainable, the measure of the deficit would be simple. Since a country's reserve of gold is necessarily finite, and a gold outflow could not be continued indefinitely, the gold drain would serve perfectly to measure the deficit. But in the real world, a country keeps reserves in other forms; moreover it may not be able to count upon an indefinite flow of receipts from some of its operations. On these accounts, the measure of the deficit of even a simple nonreserve-currency country is open to question. Most countries implicitly assume, when settling their accounts, that they are unable to increase their net short-term liabilities, but that they can continue to import long-term capital indefinitely. Accordingly, they treat their long-term capital imports as above-the-line receipts; while they put their *net* short-term capital imports below the line, regarding them as a method of financing their deficit. But these assumptions appear to be less than fully convincing. A moderate increase in short-term interest rates perhaps is all that is needed to stimulate short-term capital imports; it may be far more difficult to encourage the import of long-term capital. And there is no reason to suppose that a so-called long-term capital

import is less likely to be quickly reversed than a short-term one. Although it may be convenient to distinguish between sustainable capital imports and others by classifying all long-term capital imports under the former heading, and all short-term capital imports as temporary, such a criterion, unfortunately, can be decidedly misleading. Nevertheless, as we have said, many countries tend to follow it.² Thus, measuring the deficit in a meaningful way for the ordinary country is by no means as simple a task as we frequently suppose. And it is doubtful whether the deficit as it is commonly measured really provides the clear evidence for disequilibrium that we want. But we might note in passing that for such a country the liquidity concept is quite inappropriate.

When the task is that of measuring the deficit for the reserve-currency or banker country, the difficulties are multiplied. The characteristic of the banker country is that its short-term liabilities constitute a special kind of asset for private and official institutions abroad. And not only does the banker country supply such an asset (analogous to the commercial bank's role in making demand deposits available), but it also directs "finance"; after collecting it from a large number of sources it divides it amongst the various claimants. Presumably the accounts of the banker country should then be different too because they should reflect the special value its short-term liabilities to other countries possess for the claimants. Incidentally the Bernstein Committee, which was aware of the special role of the United States, argued that we should adopt the official settlements concept partly because we would, by doing so, be making use of the concept now employed by many other countries. But other countries are not reserve-currency countries, and it makes no sense to urge the United States to keep its accounts as they do.

If there were a complete acceptance by other countries of the U.S. role as banker, it would be proper to treat a rise in our short-term liabilities to others, whether to private or to official institutions, as an above-the-line capital import. Indeed, the Bernstein Committee accepts this much of the argument, at least for everything but our liabilities to foreign official monetary institutions. It recommends that a rise in foreign short-term private, or official but nonmonetary, claims against us be treated as an above-the-line capital import. But if this much of the argument is valid, there is no reason for treating an increase in the short-term (or long-term) claims of foreign official monetary institutions differently. Central banks, having regard to their responsibilities, have as much reason for accumulating reserves as private firms. If they hold their reserve in dollars, an increase in our dollar liabilities to them is no less sustainable than is an increase in dollar liabilities to private firms. To argue that the private firm has a liquidity motive for permitting its dollar claims to accumulate while a foreign central bank allows its dollar claims to increase only in order to prevent an appreciation of its currency is to pretend that the cen-

² Some countries base the classification upon whether the capital importer is official or private, with capital inflows to private individuals and institutions being treated as sustainable while an increase in foreign claims of official institutions is not. But this is no easier to justify.

tral bank is a purely passive recipient which has no need for reserves of the reserve-currency. But this is scarcely compatible with the view that the United States is the reserve-currency country. For this reason, I believe that the distinction between an increase in the claims against us of foreign official monetary institutions and of all others is not helpful.³ For the reserve-currency country some increase in liabilities whether short term or long term and whether to official or private institutions should be regarded as an above-the-line capital import. But this does not mean that every increase in these liabilities should be treated in this way, without limit.

While it may be true that any country or institution would prefer larger reserves to smaller, other things being equal, too rapid an increase in (or too large a volume of) reserves can be damaging. Reserves can be too high just as they can be insufficient, and the bank or the reserve-currency country must exercise responsibility to keep them at the appropriate level. It is this consideration that should determine how much short-term capital the reserve-currency country should import. If it increases its short-term liabilities at a more rapid rate than this, it creates a disequilibrium situation, and its *excess* of short-term capital imports should be put below the line. And if it imports the proper amount, and thus generates the proper increase in foreign reserves, its balance-of-payment accounts should be in equilibrium whether the creditors are private or public, monetary or not. But if we were to follow the Bernstein Committee, and were to place all short-term capital imports except for those from foreign official monetary institutions above the line, our measures could point to equilibrium even though the increase in world reserves were far too fast or were quite inadequate.

The objection will undoubtedly be raised that we have no way of determining how large the world's reserves ought to be. Admittedly the decision would be somewhat arbitrary, just as it is for those who set domestic monetary policy; but the mere fact that an element of judgment is needed does not sentence the monetary authority to immobility. And in the brave new world of the Triffin, or Roosa, or even the Bernstein Plan, decisions like these would have to be taken.

There is another limitation to which we should be responsive at the present time. Some countries, France for example, are willing to hold only a limited amount of dollars in their official reserves. This means that for such countries the dollar does not fully serve as a reserve currency.⁴ Then, short-term capital imports from France's monetary institutions would have to be placed below the line. But this would not be a problem, since a central bank which is unwilling to add to its dollar reserves presumably converts them into gold directly. So even in our imperfect world the conclusion would remain unchanged.

³ A second objection to the Bernstein Committee's suggestion is that these claims are shifted from foreign central banks to their commercial banks and vice versa, for reasons which have nothing to do with us or our policy. And yet with every such shift our balance of payments would be affected.

⁴ Insofar as France's private firms are prepared to hold dollars, the dollar is of course a reserve currency.

U.S. short-term capital imports, from whatever source, ought to be put above the line so long as they are not excessive in terms of the need for reserves of foreign private and official institutions. Only the excess belongs below the line. And it is no more arbitrary to decide that short-term capital imports of less than, say, \$800 million a year be put above the line than it is to classify *all* short-term capital imports except those from official monetary institutions as above-the-line entries; it is no more arbitrary and it makes more sense.⁶

The Bernstein Committee has without a doubt performed an invaluable service—to the formulation of policy and to economists too. I hope there will, however, be a next step in which the official settlements concept is replaced by one which comes closer to providing a measure of the distance from disequilibrium of the reserve-currency country. We have still, I believe, a good way to go.

LORIE TARSHIS

Stanford University

Money in the International Order. Edited by J. CARTER MURPHY. Dallas: Southern Methodist University Press, 1964. Pp. ix, 110. \$3.00.

Hardly a week passes without the publication of a new monograph, collection of essays, the results of a conference or symposium, or hearings before a Congressional Committee, etc., on the subject of the international monetary system, balance of payments, international liquidity, and all that. The present volume contains lectures by Walter S. Salant, Frank A. Southard, Jr., Lawrence B. Krause, Robert A. Mundell, Attiat A. Farag and David J. Ott, presented at a conference on these problems in March 1964. For the expert, the meat is in the essays of Salant and Mundell. Southard's paper, "International Monetary Arrangements," gives a short, readable but nontechnical description of the basic institutions and modes of operation of "the international monetary system today." Krause discusses on twelve pages some implications for the demand and supply of international liquidity of "the fact that five of the world's convertible currencies are issued by countries joined together through the Treaty of Rome"—a fact that is, in his opinion, often overlooked but turns out to have precious little to do with international liquidity, at least at the present stage of integration of the EEC countries. The paper by Farag and Ott, "Exchange Rate Determination Under Fluctuating Exchange Rates: Some Empirical Evidence," presents in eighteen pages the results of a few econometric exercises. The conclusion that "the study does not yield many sweeping generalizations" shows disarming modesty, but is in fact an overstatement.

Salant's article, "Does the International Monetary System Need Reform?"

⁶ Bernstein in his testimony before the Subcommittee on Statistics of the Joint Economic Committee (May 11, 1965) stated: "But I think that by the definition of the Balance of Payments Division, some deficit between \$500 million, say, and a billion dollars, might be regarded as an average over a long run that could be sustained by the economy indefinitely without any adverse consequences." While his figure seems small, since it would provide for a growth in world reserves of no more than $2\frac{1}{2}$ to $3\frac{1}{2}$ per cent a year, it does at least imply that an estimate is possible.

(the longest in the series, thirty pages), is an able, succinct, and useful summary, elucidation, and defense of the well-known Brookings book, *The U.S. Balance of Payments in 1968*, and touches on all the major problems. He defines the functions of an international monetary system: It should not interfere with free trade and payments and should provide sufficient liquidity without endangering full employment or price stability. Then the present system is tested in the light of these criteria and is found wanting. Its defect is that it does not supply sufficient liquidity. The meaning of adequate liquidity is carefully discussed and the conclusion reached that international liquidity has been scarce already "for some years." "I accept the definition that 'adequacy' means an amount of liquidity which permits the sum of the subjective valuations of excessive accumulations to equal the sum of subjective valuations of deficiencies" (p. 25)—hardly an operational definition. "This definition implies that liquidity is insufficient if it does not put as much pressure on surplus countries to reduce their surpluses as it puts on deficit countries to reduce their deficits." "This condition exists now."

It has been objected that the surplus countries in Europe have actually accepted a good deal of inflation, i.e., "much pressure was put on them." The author's counter argument is that they should reduce import barriers, contribute more to defense and to aid to less developed countries. While he is right that these steps would at the same time relieve inflation in the surplus countries, unemployment in the deficit countries, and the balance-of-payments disequilibria, it is really not very helpful to suggest all sorts of structural reforms and basic policy changes, desirable as they may be, to justify inflationary demands for increasing international liquidity.

The adjustment mechanism is not discussed at great length. Exchange flexibility is rejected and it is assumed that the mechanism works, but works slowly. Hence large reserves are required to provide sufficient time for smooth adjustment. In that, the Brookings group agrees with the gold standard advocates who, too, blame the fractional reserve system. Both are subject to the criticism that, if countries are somehow provided with large reserves, at least some of them will spend at least part of their reserves and go back to the fractional reserve system. Salant is aware of this difficulty but argues that the developed industrial countries have and will show sufficient discipline to withstand that temptation. I cannot share that optimism and it would be easy to quote cases where large reserves have been lost in a few years through inflationary policies. But this does not alter the fact that Salant's is a stimulating and thought-provoking contribution which will force many readers to rethink and reappraise problems that they had already put away in their minds as having definitely been solved and needing no further consideration.

While Salant deals primarily with the liquidity problem, Mundell concentrates entirely on the problem of adjustment which he calls, quite rightly in my opinion, the more fundamental and difficult of the two. He contrasts the fixed rate with flexible exchange rate systems, both with respect to spot and forward rates. The present system is really a mixed one, because only spot rates are fixed while forward rates are free. But in my opinion, the author should have pointed out that the flexibility of the forward rate lends only very

little flexibility to the system as a whole, because the forward flexibility cannot amount to much so long as the spot rate is fixed and is generally accepted as unalterable.

But the core of Mundell's contribution is the attempted demonstration that the relative effectiveness of monetary and fiscal policies in stabilizing employment and equilibrating the balance of payments is radically different under the system of fixed rates and the system of flexible rates, *if there is free international mobility of capital*. It may strike the reader as paradoxical that, given the italicized condition, under fixed rates the effect of monetary policy on employment is said to be nil while fiscal policy is highly effective, whereas under flexible rates it is the other way round. The reason why this sounds paradoxical is that we are not used to assuming perfect mobility of capital. If it exists, it means that under fixed rates an attempt on the part of the monetary authorities to tighten money simply leads to large capital imports, a result which improves the balance of payments but leaves the supply price of capital unchanged and hence does not stimulate employment. Similarly, an attempt to ease money simply chases capital out of the country, thus changing the balance of payments but having no effect on employment.

It certainly is useful to think through these various cases. But in practice capital is never perfectly mobile and there are, of course, different types of money capital (short term, long term, mortgage capital, etc.) with different degrees of mobility. It would, therefore, be dangerous if central bank governors and ministers of finance took the author's advice literally and memorized and applied mechanically the rules which he lays down in a "policy table" on page 73. Also, the application to the Canadian policy between 1959 and 1962 seems to me misleading. The author is certainly right when he says "that the Canadian experience brought discredit to the flexible exchange rate system—unjustly because the *system* was blamed instead of the *inappropriate policies followed under the system*. In 1959, when Canada experienced severe unemployment, monetary policy was tightened" (p. 73, italics in original). Assuredly, to tighten money and raise interest rates in a depression is perverse. But it would have been perverse also under a fixed rate system. Easy money plus a budget deficit would have been the right policy whilst the author says credit should have been expanding "... to reduce the budget deficit" (p. 74).

But despite a certain oversophistication, which makes it dangerous advice to less sophisticated policy makers, Mundell's paper is exceedingly stimulating for a theorist. There is a useful appendix setting out in ten points the arguments against flexible exchange rates and the rebuttal.

GOTTFRIED HABERLER

Harvard University

Multilateral Commercial Diplomacy—The General Agreement on Tariffs and Trade and Its Impact on National Commercial Policies and Techniques. By GERARD CURZON. London: Michael Joseph, 1965. Pp. xii, 367. 60s.

This thorough study of the General Agreement on Tariffs and Trade begins with a short historical introduction. Chapter 2 discusses the organization of

GATT, Chapter 3 the most-favored-nation clause, and Chapters 4 and 5 tariff problems. Barriers to trade other than tariffs are discussed in two succeeding chapters: quantitative restrictions in Chapter 6, agricultural protection in Chapter 7. The next three chapters are devoted to GATT actions in the fields of economic development, economic regionalism, and state trading. The book concludes with a brief discussion of prospects, including GATT's relations to INCTAD.

Although the author announces early that he will resist the temptation to enter into the welfare theory of international trade, the book abounds in welfare pronouncements, by no means confined to international trade. (E.g., there is talk of the "vicious circle of planning" in underdeveloped countries; "non-collectivist countries' trade assures that factors of production are used to their optimum within the nation. This principle is extended to foreign trade as well. . .") And we are told that "a good case can probably be made for substituting unilateral trade concessions for aid by the rich countries.")

In spite of the author's belief that economic theory has established the case for free trade (which he supports by mutually exclusive arguments as if they were additive), while political obstacles prevent the realization of this ideal, the case for GATT and freer trade is probably philosophical and political rather than economic.

A system of rules on which a large number of countries can agree, so the argument runs, must be simple. More complex rules, though they may be preferable on economic grounds, are more open to abuse and more difficult to police. It is presumably for such reasons, rather than on theoretical grounds, that discrimination in favor of nationals is permitted, while discrimination between foreigners is prohibited; that 100 per cent preference is permitted in free trade areas and customs unions, while anything short of it is ruled out; or that preferential free trade must apply, in principle, to all products and must not be confined to, say, new production. (The interpretation of the new Chapter 4 is still too uncertain to cast doubt on this statement.) It is well known that none of these principles can be justified by welfare *economic* arguments. Discrimination in favor of the domestic market makes nondiscrimination between foreigners no longer optimal; partial preferences are more likely to be beneficial than 100 per cent preferences, etc. Even more difficult to understand is the rule that, temporary restrictions apart, protection should be provided exclusively through tariffs, not through other commercial measures. Not only economic but also political arguments point to the advantages of subsidies over tariffs (and surcharges over quantitative restrictions). But Gerard Curzon has not yet even advanced to the Neo-Panglossian position that all is for the second-best in the best of all feasible worlds (and everything in it is a necessary constraint). Nor is the author more convincing in his attempt to persuade us that the GATT bargaining procedure is the most promising approach to freer trade. He does not meet the difficulty that in the bargaining process high-tariff countries have an advantage over low-tariff countries. This means not only a conflict of interests but also a built-in tendency to resist tariff reductions, which would weaken future bargaining power.

Not only the economic but also the *philosophical* argument for simple and

general rules is fallacious. The political philosophy of GATT is founded upon a long-standing confusion, of which even such a clear-headed thinker as David Hume is guilty. Hume contrasts the highly specific reactions when we are seeking our own self-interest with the "universal and perfectly inflexible" laws of justice. He seems, like many others (including GATT), not to make a necessary distinction between *general* principles (the opposite of specific ones and therefore necessarily simple) and *universal* principles (which may be highly specific and highly complicated, provided that they contain no uneliminable reference to individual cases). Thus, Hume says, in one place "universal and perfectly inflexible," but lower down "general and inflexible." And the use of the word "inflexible" conceals a confusion between a principle being able to be *altered* (which has nothing to do with its universality or generality) and its having a lot of exceptions written into it (which is consistent with universality but not with generality). Hume evidently thinks that the rules of justice have to be simple, general ones. He argues that unless the rules are *general*, people will be *partial* in their application of them and "would take into consideration the characters and circumstances of the persons, as well as the general nature of the question . . . but this would produce an infinite confusion in human society, and . . . the avidity and partiality of men would quickly bring disorder into the world, if not restrained by some general and inflexible principles." But this is fallacious. In order to prevent people from being partial, the principles have to be universal, i.e., not contain references to individuals; they may, and indeed should, not be general; surely our judgments based on them *ought* to "take into consideration the characters and circumstances of the persons, as well as the general nature of the question."

Like Hume, the philosophy of GATT, by confusing "general" with "universal," arrives at the wrong conclusions of the need for simplicity. A highly complex system of multi-tier preferences may well be best and most just for a group of developing countries at different stages of development entering into a union.

The descriptive content of the book is valuable. History, institutions, and the adaptations of GATT to new requirements are admirably set out in great detail, and the author has brought together material previously dispersed over a large number of sources.

Germany's Economic Dilemma: Inflation and the Balance of Payments. By PATRICK BOARMAN. New Haven: Yale University Press, 1964. Pp. 344. \$7.50.

This is an extremely interesting study of Germany's problems in coping with the inflationary consequences of its enormous export surpluses in the 1950's. It provides a fascinating case study of the difficulties encountered in trying to combine independent domestic monetary-fiscal policies, fixed exchange rates, and an equilibrium in international payments. It gives us not a chronicle of events, but a thoughtful discussion of the policy issues as they ap-

peared to German economists and the monetary authorities at the time. It is particularly successful in communicating the *flavor* of the German balance-of-payments controversies as they occurred.

Professor Boarman's own retrospective judgments on those controversies and his own analyses and generalizations about the substantive economic issues involved, while evincing wide scholarship, dialectic skill, and an expert handling of both statistical and historical data, seem, nevertheless, distinctly less original and less successful, on the whole, than his discussion of the evolution of German thought about the problems. He unduly ignores broad sociopolitical factors that were overlooked by all sides in the technical economic controversies. Moreover, the book's fiery ideological commitment to the *Soziale Marktwirtschaft* philosophy of Ludwig Erhard and Wilhelm Röpke (which is invariably shown as providing the right answer) gives it a somewhat doctrinaire character.

Germany's export surpluses were truly enormous. From 1952 to 1961 they averaged (in goods and services) 3 per cent of GNP—about five times the U.S. ratio. Boarman argues that they resulted in the first instance from the practice of the neoliberal economic philosophy, which by means of tight money and budgetary surpluses, stabilized prices, stimulated private saving and investment, but made it easier and more profitable to sell in foreign than in domestic markets. Moreover, by spurring competition and freeing the price system from arbitrary governmental controls, the German economy was made extremely flexible and efficient in discovering and responding to the particular requirements of its individual customers both domestic and foreign. Boarman's discussion of structural and nonprice factors in German export competitiveness and their relation to domestic economic policy is particularly interesting and suggestive.

These giant surpluses, however, had powerful inflationary effects which the Germans, with their deep emotional horror of inflation, were determined to avoid. The monetary authorities therefore raised interest rates very high and the government ran large budget surpluses. The high interest rates attracted an inflow of short-term capital, adding still further to the balance-of-payments surplus and requiring further credit stringency to sterilize the expanded monetary base. The large budget surpluses and the tightening of domestic credit restrained domestic purchases and costs, discouraging imports and spurring exports—on which profit margins were higher and which could often be financed by foreign funds. In short, the effort to combat inflation by traditional means resulted in the "import of inflation" from Germany's neighbors who were pursuing more expansionist monetary policies. This put the German authorities in an apparently insoluble dilemma. Not only did the attempt to fight inflation apparently result in still more inflation, but it drew criticism from abroad that Germany was not acting either by the old gold standard "rules of the game" or by the new standards of "a good creditor." Furthermore, it involved restraining domestic consumption and investment in Germany for the benefit of countries which in most cases had higher consumption levels and more capital than Germany.

"A most ingenious paradox" to all appearances! And there is much truth in this picture. Is it, however, the whole story? Despite Boarman's persuasive presentation, I cannot really believe that the Germans very much wanted to give up their export surplus or that they would have faced any insuperable difficulty in doing so.

Consider the first point. According to Boarman: "Nothing could have been farther from the truth than the assertion that the Germans were anxious to add to their holdings of gold and exchange. Their incessant concern, as has been shown, was to get rid of such 'wealth' where this could be done without producing a domestic inflation. If Germany were a miser, she was, like Midas, more deserving of sympathy than of anger" (p.251). To me, this view seems naïve. To be sure, certain German economists and public officials said such things. But one risks major error if one ignores the psychological-political contexts in which economic policy is made. The book completely abstracts from the fact that Germany, a nation with a formidable power-drive, had just lost a disastrous war and been deprived of decisive weapons. It seems entirely unreal to discuss German economic policy without realizing that Germany turned naturally to the pursuit of power by the one means left fully open to her—both on the individual and on the collective level—namely by the acquisition of wealth. In this context it is easy to understand both the high level of saving among individuals, and the major national effort made by Germany to re-establish itself as a financial power by acquiring large stocks of gold and foreign exchange. Such accumulation had of necessity to be at the expense of current consumption—but a restoration of power had an unquestioned priority. Some restraint in consumption was not too painful in any case in view of the great improvement achieved over early postwar levels. A too-flamboyant rise in consumption levels, moreover, might have been resented by Germany's neighbors whose own economies had been damaged by German attack and occupation, and whose citizens had accepted taxation and restrictions to help restore the German economy and defend its security.

Boarman incidentally fails to indicate the extent to which the German export surpluses can be explained by allied military contributions to her defense. Relevant data, which are introduced only in connection with a minor point (the possible disadvantages of revaluation), and the broader significance of which is not discussed, show that *receipts from foreign troops accounted for 40 per cent of net surpluses on goods and services* in the period 1951 to 1960 (Table 23, p.293). The book does not mention at all that as a result of allied contributions to Germany's defense, Germany spent only 3.5 per cent of GNP on defense during these years, compared to 6 per cent by France, 7.5 per cent by the U.K., and 10 per cent by the United States. This 2.5-6.5 per cent of GNP saved on defense relative to her main commercial rivals—much of which directly benefited her balance of payments and burdened those of her rivals—will certainly go a considerable way to explain how it was possible for Germany to achieve her export surplus of 3 per cent of GNP in these years.

I also find it hard to believe that Germany could not have found the means to reduce her export surplus if she had been determined to do so. Boarman

spells out in great detail the multitudinous objections to various adjustment policies that might have been adopted. They do not seem to me to be decisive: essentially they add up to an unwillingness to pay the cost of abandoning the export surplus. It is admitted for example that the export surplus was largely based on an abnormally low German propensity to import—in turn resting on the very low import content of German exports, and the abnormally low ratio of consumption to GNP. All the more reason, one would suppose, for eliminating import barriers. Boarman's main argument here is that Germany led its neighbors in liberalization and tariff reductions. This is true, but doesn't quite answer the point: if Germany had been really determined to end its export surplus it could have gone even further and faster, especially on agricultural imports.

Similarly, more effective measures could have been taken, one would suppose, to reduce the severe inequality in income distribution in Germany and to reduce unemployment (which stayed above 3 per cent until after 1958), with benefit to personal consumption and imports. Such measures could have been justified under the social justice aspect of the *Soziale Marktwirtschaft* philosophy. Röpke's argument that unemployment could not be further reduced until there were more savings and capital seems absurd; temporary public works projects of low capital intensity, and credits to finance imports of the required equipment for private projects could certainly have helped—if there were a real willingness and desire to sacrifice the export surpluses. The real emotional objection to such policies comes out in comments on the unreasonableness of expecting surplus nations to adjust themselves to the inflationary developments in the deficit countries rather than vice versa.

As for the frequently heard request that Germany reduce its surpluses by contributing more to foreign aid, this is parried by the explanation that the German export surplus *was* an indirect contribution to foreign aid: i.e., by shifting resources to the aid-giving nations, the accumulation of U.S. dollars in German reserves was "equivalent to an involuntary financing by the Germans of portions of American military and economic aid programs"—programs which they themselves would sometimes have rejected. It is also argued that Germany was too deficient in capital (as proved by the high interest rates) to afford foreign aid.

One final prescription—of a wholly orthodox type—was always available, but continuously rejected until 1961, and then adopted only in a homeopathic dose. This was the prescription of an upward currency revaluation, advocated by Röpke as early as 1956, and held off, Boarman admits, largely through the implacable political opposition of the export interests and their banks. Can one believe, then, that the politically dominant forces in Germany really wanted to rid themselves of their export surpluses or were really displeased by the rise of Germany, by 1955, to the position of the second country in the world in the size of its gold and foreign currency reserves?

EMILE BENOIT

Columbia University

Japan and the United States in World Trade. By WARREN S. HUNSBERGER. New York and Evanston: Harper & Row, 1964. Pp. xvii, 492. \$6.00.

"This study of Japan's foreign economic relations seeks to illuminate not only the Japanese side of the story but also American interests and the issues of American policy involved" (p. vii). The main focus is on the period 1952-62 (the cut-off for statistical data). Subsequent events have not altered substantially the trends detected by the author or the validity of his policy conclusions. Warren Hunsberger emphasizes the overwhelming economic significance of the United States for Japan as its largest trading partner, main foreign source of new technology and capital, and perhaps most important as patron in international economic relations. Japan has become of increasing political and economic importance to the United States as well. America's thirteenth largest trading partner in 1952, Japan in the past few years has been second only to Canada.

Part I, "Japan in the World Economy," uses Japan's postwar balance of payments as the framework for discussion. The author stresses the structural importance of imports as inputs for Japan's industrial production process, and of foreign capital and foreign technology. Most of the discussion centers on the nontrade components of Japan's balance of payments: U.S. military and economic aid, special procurement, reparations, various kinds of short-term and long-term capital inflow, and arrangements for the inflow of foreign technology. Part II, "Japanese Commodity Trade," straightforwardly describes the growth, commodity and geographical composition, controls, prices, and policies of Japanese imports and exports. Two following chapters treat the U.S. market for Japanese goods in general, and cotton textiles in particular.

In Part III, "Policy Needs and Possibilities," Hunsberger begins by stating in rather broad, policy-oriented terms the general desirability of trade liberalization and specialization based on comparative advantage. He then examines Japan's reservations against trade liberalization, and points out that Japan has become sufficiently strong that it no longer requires extensive U.S. sponsorship. Rather, it can be expected to develop its own foreign economic policy. After a discussion of the "costs" to the United States of trade with Japan, the author suggests that U.S. and Japanese economic interests are basically harmonious—both want flourishing multilateral world trade.

A striking feature of U.S.-Japan trade relations is that while most imports from the United States do not compete directly with Japanese production, almost all imports from Japan compete vigorously via prices with U.S. production. In certain industries competition has been so severe as to arouse strong cries of market disruption and attempts to obtain protection. Hunsberger examines the resultant action on tariff and quota restrictions, and on the Japanese development of the "voluntary" export quota system in hard negotiation with the U.S. government as representative of the cotton textile and other industries. Export quotas are easier to adjust and to expand than other forms of trade restriction, but they too are restrictive. The proper evaluation of export quotas depends on whether protectionists could have obtained other restrictions. Hunsberger is not clear, but seems to feel that U.S. protectionists would

have won the day in the late 1950's. Japan has opened a real Pandora's Box, with producers of other commodities and other countries pressing for similar limitation on exports by exporters. This technique may well presage the way in which the high-income countries will handle the imports of highly competitive, labor-intensive manufactured goods from low-income countries. Indeed, as Hunsberger points out, the nominally liberal but in practice protectionist international cotton textile agreement bodes ill for the poor countries.

Writing style (avoidance of technical economic terminology) and the general level of discussion suggest that this book was written for an audience of intelligent laymen. The author provides a welter of factual descriptive detail, involving exhaustive synthesis of data and analysis from a variety of sources. A statistical appendix and an extensive bibliographic note on English-language materials (many of which emanate from Japan) are particularly useful reference materials. From all this Hunsberger has rather loosely drawn some general policy conclusions and recommendations. These reflect more the author's liberal trade position and optimism than a detailed analysis of costs and benefits of particular policies. Nonetheless, I find his conclusions reasonable and full of common sense: Hunsberger presents a good case to his audience.

Economists, however, will be disappointed that the author does not go much beyond conventional wisdom or, despite the masses of data, engage in close empirical analysis of a number of important questions underlying policy issues, instead of simply relying on general comments and assertions. For example, there is no estimate of what the inflow of imports from Japan would be in the absence of (a) export quotas, and (b) tariffs and other forms of restriction; i.e., the nature of the supply schedules in U.S. import-competing industries. Nor does he examine the degree to which resources in these industries are mobile. Is Japan's policy of restricting foreign direct investment rational, in that it can achieve the same objectives more cheaply by purchases of technology and portfolio capital inflow? Precisely (or even roughly) how important has foreign technology been in the growth of Japanese exports and GNP? How has Japan achieved such a successful export performance? Hunsberger explains only by general reference to comparative advantage, low wages combined with a high level of technical skill, Japanese behavior patterns, and the like.

I found the resolution of certain policy issues unclear. Hunsberger urges Japan to engage in more foreign aid, yet notes that the inability to pay for the level of imports needed will continue as a major constraint on Japanese growth. He does not resolve this apparent contradiction. Or another issue: should I, sharing the author's liberal trade persuasion, favor export quotas or not? We cannot blame Hunsberger for giving no full answer, since obviously much in a practical policy sense depends upon the strength of the protectionist forces on any particular issue at any particular point in time. Hunsberger does make sensible suggestions on procedures for arriving at export quotas and for built-in expansion of quotas, if export quotas are the only viable alternative.

In summary, this book is useful to economists mainly for its descriptive detail, as a data and reference source, and for its broad delineation of policy fa-

cets of Japan's trade relations, particularly with the United States. Analytically it is not strong.

HUGH T. PATRICK

Yale University

Integración de América Latina—experiencias y perspectivas. Edited by MIGUEL S. WIONCZEK. Mexico: Fondo de Cultura Económica, 1964. Pp. xxi, 381.

The purpose of this book of essays is to provide the nonprofessional Latin American reader with a description and evaluation of the "perspectives and possibilities" of Latin American integration and to give wider currency to the influential body of ideas on regional integration formulated by the U.N. Economic Commission for Latin America (ECLA) during the 'fifties under the leadership of Raúl Prebisch. The editor has brought together eighteen essays of varying quality written by well-known Latin American and non-Latin American economists who share an outlook uncritically sympathetic to what can be called the "ECLA doctrine" on regional integration. The book joins the growing *corpus* of literature available in Spanish on the theoretical and practical aspects of economic integration in less developed areas. (e.g., *Problemas de Pagos en América Latina*, CEMLA, 1964; *Cooperación Financiera en América Latina*, CEMLA, 1964; *Coordinación Monetaria Regional*, CEMLA, 1963; S. Dell, *Problemas de un Mercado Común en América Latina*, CEMLA, 1959; B. Belassa, *Teoría de Integración Económica*, UTEH, 1964).

The book is divided into three sections. The three essays in the first section (B. Belassa, S.B. Linder, and H. Kitamura) deal with theoretical approaches to regional integration. In the second section on the Latin American Free Trade Association (LAFTA), four essays review the history (M. Wionczek), the actual operation (S. Dell and G. Magariños), and problems (R. Prebisch) of LAFTA; three essays cover specific sectors: industry (P.G. Reynoso and J. Tinbergen) and transportation (Enrique Angulo H.); five essays concentrate on questions of financing LAFTA integration (F. Herrera, R.F. Mikessell, and E. Galveas) and proposals for a regional payments system (B.N. Siegel and R. Triffin). The final section includes three essays analyzing economic integration (J. Moscarella), industrialization issues (J.C. Mills), and payments arrangements (J.G. del Valle) in Central America. Appendices provide complete texts of the treaties establishing LAFTA and the Central American Common Market. A brief bibliography on regional integration completes the volume.

The principal value of *Integración de América Latina* lies in the ideas and notions of ECLA which provide the basis for many of the arguments of the essays and which have been so influential in technical and official circles in Latin America and elsewhere. The ECLA doctrine can be summarized as follows: An external sector "bottleneck" is retarding Latin American economic development. Primary commodity exports (due to a secular decline in the terms of trade and protectionist policies of the industrial countries) are lag-

ging behind the rate of growth of imports creating a structural payments disequilibrium. Latin American capital formation depends, to a considerable extent, on the capacity to import investment goods, technology, and raw materials, which is not growing fast enough to achieve a satisfactory growth rate. Therefore, economic development is impossible without import-substitution industrial expansion, which reduces nonessential imports and conserves scarce export income to pay for essential imports. However, the easy stage of import-substitution policy has come to an end in much of Latin America; it is now more difficult and costly for a single country with a limited domestic market to substitute local production for *essential* imports. ECLA's remedy is the creation of a Latin American political-economic bloc which will permit further import-substitution vis-a-vis the rest of the world and offer an alternative to inefficient industrialization by promoting liberalized intra-regional trade and specialization. Furthermore, the formation of LAFTA increases the bargaining power which Latin American countries can bring to bear on the developed countries to obtain nonreciprocal tariff reductions for primary commodities and preferential treatment for regional industrial exports. Thus, Latin American integration is an important part of ECLA's development strategy aimed at overcoming the "external bottleneck" via industrialization and improving Latin America's terms of trade.

The most serious shortcoming of the book is that not a single essay questions the soundness of the assumptions on which the ECLA doctrine rests. The Prebisch-Singer thesis which predicts the secular decline of the terms of trade of primary producers based on alleged past trends is accepted as an article of faith in spite of the scepticism aroused by the works of Morgan, Kindleberger, Lipsey, and Haberler. The overemphasis on import-substitution and the neglect of the relevance of comparative-cost considerations in the formulation of a Latin American development strategy continues to be a central weakness of ECLA doctrine. Demand deficiency (lagging external demand) is stressed to the virtual exclusion of supply deficiency (lagging domestic supply) resulting from government policies (taxation and overvalued exchange rates) which discriminate against primary producers. Together with nationalist *ressentiment* against the traditional, upper-class agricultural-export sector, the ECLA approach has helped to create the exaggerated prejudice against primary exports in official circles which hampers economic development in many Latin American countries.

Business Organization; Managerial Economics; Marketing; Accounting

Soviet Management—With Significant American Comparisons. By BARRY M. RICHMAN. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1965. Pp. vii, 279. \$5.95.

Professor Richman in this book is concerned with describing the organiza-

tion and planning of Soviet industry viewed from the perspective of the individual Soviet enterprise. His primary concern is with the attitudes and behavior of enterprise managements, but these are discussed within the context of macroeconomic problems.

The novelty of the book is twofold. One is that the Russian sources used are entirely of postwar origin. The second is that, in the course of trips to the Soviet Union during 1960 and 1962, Richman visited more factories (16) than has any other Western writer on the same subject.

This is the fifth English-language book which has treated this subject. The first three dealt entirely with the period prior to World War II (G. Bienstock, S. M. Schwarz and A. Yugow, *Management in Russian Industry and Agriculture*, 1944; D. Granick, *Management of the Industrial Firm in the USSR*, 1954; J. Berliner, *Factory and Manager in the USSR*, 1957); the fourth (D. Granick, *The Red Executive*, 1960) also leaned heavily on prewar materials although it was significantly supplemented by postwar Soviet writings and interviews. Given this rather extensive literature, one might have expected Richman's book to be heavily oriented toward showing continuities and discontinuities between prewar and postwar Soviet management. In fact, however, Richman virtually ignores this theme. Curiously, his footnote references mention only two of the four books—and one of these is mentioned only with regard to subject matter which is virtually untouched by Richman.

Richman's book might be viewed as having added value because of its inclusion of comparisons with American managerial behavior. Some of these are rather interesting, although quite limited in scope. Again curiously, no indication is given that similar comparisons are provided in the literature cited and in an article by Berliner.

The scholarly contribution of this book would seem to lie in its indications of change between the prewar and postwar eras of Soviet management. Richman's key statement here seems to be that Soviet enterprise managers have acquired greater authority and independence since the middle-1950's. This may indeed be the case, but no documented evidence whatsoever is presented in support. At least one of the supporting but undocumented claims (that, particularly during the Stalin era, personnel problems were not of significant concern to enterprise managers) is clearly incorrect. Presumably, the source of Richman's view as to the growth of power by enterprise managements consists of his interviews. But the results of such interviews, when they relate to such a broad position, can scarcely be accepted as authoritative without close examination. This Richman makes no attempt to do. Although it is mentioned in another connection, a major article by A. Nove (in *Soviet Studies*, July 1962) is completely ignored in this context despite the fact that it presents evidence which, on the face of it, casts doubt on the Richman thesis.

Judging from the materials presented, this reviewer would conclude that the position of Soviet enterprise-managers did not change particularly between the prewar period and the experiments of 1964. If this conclusion is correct, then, aside from institutional shifts such as the change to the regional system of administering firms which occurred in 1957, one might properly conclude that the earlier Berliner and Granick monographs are still up-to-date descriptions

of Soviet reality. However, this reviewer feels no great confidence in such a conclusion. For, out of three major areas of potential change, one is virtually ignored (control over the enterprises by the State Bank) and the other two are examined so sketchily as to inspire no confidence whatsoever in the results obtained. These two areas are those of Party relations with enterprise management and of management backgrounds and careers.

According to the flyleaf of the book, Richman is writing for both specialists and nonspecialists. For the former group, some tables are worthy of attention—although these are based on a very tiny number of enterprises in which Richman carried on interviews. These are presented on pages 67-68, 135, 161, and 212. Other interesting data are presented on pages 167-68 and page 176. However, even the table on page 135—which deals with bonus payments to management, and which this reviewer finds the most interesting of all—suffers seriously from a failure to define “management”; one can think of three alternative definitions and there is no inkling of which is intended. Some other specific statements of fact (on pages 66 and 92 especially) may well be correct and are quite interesting if they are reliable; but since they are left totally unfootnoted, the specialist can hardly pay them much attention.

As for the nonspecialist, other works cover much the same ground and are written in a more interesting style. Richman's book also suffers from the absence of an index.

Law and Economic Policy in America: The Evolution of the Sherman Antitrust Act. By WILLIAM LETWIN. New York: Random House, Inc., 1965. Pp. vi, 282. Appendix. \$5.95.

This is one of those rare studies that slip back and forth between diverse but related fields of scholarship and between pure methodological issues and those of empirical substance. The effort and the results justify William Letwin's often tedious excursion into legal and constitutional history, the history of economic doctrine, and the pragmatic background of legislating economic policy. His search has been into the primary sources, especially the legislative debates and the over-all effect is quite impressive. I have no hesitation in hailing Letwin's study as a model of how to study the historical development of national economic policy.

Letwin has three points to make. First, the Sherman Antitrust Law of 1890 was much more novel in its legal frame than is commonly supposed. The cliché (of the times and of subsequent text writings about the law) is that the Act codified the “common law.” Letwin clearly expands this hypothesis to one more reasonable of acceptance by delving into the common law relating to monopoly and restraints of trade and tracing its dynamic and fluctuating de-

velopment prior to the passing of the Sherman Act. Letwin also tackles another cliché common in conventional historical wisdom: passage of the Sherman Act was a crumb thrown by Congress to a hungry public. Congress had no intention of restricting the merger movement or prescribing competitive rules of the game, historians of several generations have argued. Instead it passed a law so simple in wording as to be ineffective against the ills claimed, but so sweeping in its condemnation as to assuage an hysterical public opinion fearful of the octopus monopoly. This just wasn't so, according to Letwin. Congress grappled with the issues inherent in designing legislation to cover so broad a range of business issues and opted not for a specified bill of particulars, but for a broad statement of economic philosophy, and one which could be given substance by judicial interpretation and where the myriad and complex issues could be adjudicated on their relative merits.

Letwin's third objective is to convince the reader that legislation which regulates business conduct and prescribes limits on industry organization and structure is at best Hobson's choice. Legislation such as the Federal Trade Commission and the Clayton Acts, offered as weapons for closing the holes opened by the Sherman Act, is no less successful than broadly conceived rules of conduct and may even be worse. In short, if public opinion demands legislation which affects industry structure, conduct, and performance, such rules had best be purposefully broad and capable of relative and individual flexibility in interpreting them. What emerges from this tripartite approach is a rewarding study of the elusive nature of achieving a balance between what is equitable, what is economically rational, and what is politically feasible.

I accept without reservation Letwin's conclusions. Economic historians have just not been correct in interpreting the motives of Congress in passing the Sherman Act. Letwin's examination of the evidence is far more complete and seemingly objective and just. Similarly, economic historians have accepted, without investigation into primary sources, the supposedly intimate link between the common law and the Sherman Act. Letwin claims for the framers of the Sherman Act much more innovation than hitherto believed. His third conclusion could be stated in even stronger terms. It is not possible, I think, to accept the view that the mix of antitrust legislation in this country (starting from the fount of the Sherman Act up to the Celler Amendments) has in a measurable way influenced the performance of the entire economy, substantially altered industry structure, improved price flexibility, or aided our long-term economic growth. One can point to a few cases where results are visible though not quantifiable, but the over-all accomplishments are nominally small. Letwin's point is that this is not a surprising result. The economic philosophy embodied in the Sherman Act is so fundamental to American national character and values, however, that even if on a cost-benefit analysis the superstructure of antitrust laws cannot be vindicated, there is something comfortable to the national psyche about believing that the "robber baron" of the past could not exist today. Comforting, but wrong.

Government-Business Relations—A Pragmatic Approach to the American Experience. By ARTHUR M. JOHNSON. Columbus, Ohio: Charles E. Merrill Books, Inc., 1965. Pp. xvi, 446. \$8.75.

The novelty claimed by Arthur Johnson and the organizing theme of his textbook is a pragmatic approach to public policy. The book is arranged in five parts. Johnson discusses public policy in terms of legislative, executive, and judicial policy (Part I, 91 pages), government supports (Part II, 117 pages), government restraints (Part III, 158 pages), government ownership of productive facilities (Part IV, 34 pages), and concludes with a summary of government-business relations since the turn of the century (Part V, 29 pages). In my judgment this book suffers more from a lack of analytical depth than from scope of coverage.

Johnson, recognizing the importance of "processes by which private and public interest are adjusted to one another" (p.vii), finds descriptions of statutes and court decisions that govern business, as well as economic analysis, of limited analytical utility. He argues that the latter is "limited to our acceptance of the premises on which economic theory is built . . . the decision of legislators, judges, and administrators, not to mention the public, seem to have ignored, contradicted, or confounded economic theory" (p.vii).

A careful reading of the book, particularly pages 292-302, reveals that "the premises on which economic theory is built," are not the usual postulates used in economic theory, e.g., individuals prefer more to less substitution, etc. Rather, economic theory is erroneously equated with perfect competition. As no single evidence is cited in the book that is held to contradict economic theory, the contradiction presumably comes about when Johnson does not find all the industries conforming to perfect competition.

The author's confusion about the nature of resource allocation, the role of private enterprise, and the market system has led him to summarize the discussion of several subsidy cases in the following manner:

The point to be made here, however, is that, responding to pressure and interest groups, government is allied with a very broad range of business endeavors. In view of the overemphasis frequently given to governmental restraints on business, it is well to keep in mind the many ways in which public funds and public servants help to protect and sustain private enterprise (p. 160).

The fact of the matter is that a subsidy as well as a restraint may misallocate resources. An economist (if not the beneficiary of the subsidy) will not cheer an attempt to balance the two kinds of government actions.

I consider lack of a frame of reference for evaluating the outcome of numerous types of governmental subsidies and restraints a significant shortcoming in a text for an economic course in government-business relations. Moreover, while the organizing theme of the book is to describe processes by which public and private interest are brought together, the author says that "public policy" defies precise definition, and he does not even attempt to define "public interest."

I am sympathetic with his effort to incorporate interrelationships and to

discuss phenomena in a particular institutional arrangement, but his focus on what "works" leaves the reader with only cursory knowledge of the general topics that are usually treated in such a text. Thus, the interrelations are discussed in their legalistic setting, with little insight to the motives behind actions or reactions of different participants in the processes. For example, on pages 5-6 one reads that pragmatic public policy:

. . . involves interrelated elements, political, social, and ideological as well as economic, specific to time and place. Problems are dealt with as they arise and not in accordance with predetermined plans. Experimentation and *ad hoc* solutions are important parts of the resulting process. Moreover, the process bears not only the imprint of public officials and their personalities but also that of private citizens and groups whose actions or reactions give public policy with respect to business, whatever its form, its ultimate significance.

The book might have become more than a narrative of various events if there had been an analysis of the behavior of the participants in decision making in the nonmarket world of public commissions who are subject to the reactions of voters. Perhaps this omission was due to Johnson's undue pessimism of the utility of economic analysis. Recent advances on this front are encouraging and what appear as "*ad hoc* solutions" may become predictable if subjected to economic analysis.

In closing, I would like to raise some criticisms that apply to other available texts as well. It is all too often that "problems" are stated without critical examination; not only is government regulation or restraint assumed to be necessary, but the outcome of the governmental action is not evaluated in terms of the original goals for which the solution was sought.

Consider the case of radio frequency allocation. Only recently analysis of the episode of the 20's, the formative years leading to creation of the Federal Communications Commission (FCC), has revealed that the problem was not defined correctly. Although interference caused by simultaneous emission of radio signals was the major consideration in that period, the FCC has been empowered to decide the quantity of broadcast service that is forthcoming. Moreover, by making subscription system of sponsorship illegal, the FCC in effect has affected the quality of the entertainment and educational services made available today. Yet both officials and students of broadcasting seem to be surprised and dissatisfied with the outcome. Although the outcome is the result of the institutional arrangement chosen, the blame is put either on the broadcasters and/or the officials of the FCC for not pursuing a more "rigorous" policy.

One can only hope that problems that have concerned us will be subjected to analyses, and assessment will be made of the outcomes of different institutional arrangements.

Report of the Committee on the Economic Impact of Defense and Disarmament. Washington: Superintendent of Documents, 1965. Pp. ix, 92. 40¢.

This is the third pamphlet on disarmament published by the U.S. government.¹ The general conclusion of the two earlier studies, which were published by the U.S. Arms Control and Disarmament Agency (ACDA), was that a major depression would not result from disarmament since the economic problems are solvable with appropriate fiscal and monetary policies. With advance planning by all levels of government, by business firms, unions and other private organizations, the funds and resources released from defense spending would allow additional public and private expenditures, creating an unqualified social blessing. The fact that little advance planning had occurred was not reflected in the optimistic views expressed by ACDA.² This latest study, although recognizing that the general solutions are known, admits that the problems of maintaining general full employment and of minimizing the regional and industrial dislocations will be difficult to solve.

The scope of this report has been substantially broadened. First, the authorship includes not only ACDA, but also representatives from the Departments of Defense, Commerce and Labor, the Atomic Energy Commission, the National Aeronautics and Space Administration, the Bureau of the Budget, the Office of Emergency Planning—all under the chairmanship of Gardner Ackley, chairman of the Council of Economic Advisers.³ Second, the general topic was expanded to include a study of the economic effect of changing defense requirements. Since the regional economic impacts are similar and since the possibility of disarmament is presently quite dim, the additional breadth will make the study more useful and the expenditure of additional research funds politically more acceptable.

The first two chapters consider the size and distribution of expenditures and employment in defense and defense-related activities, outlining the problems caused by changing expenditure patterns and by the closing of obsolete facilities. As the report points out, "Readjustments are most successful when the economy is expanding vigorously and when employers and workers have strong incentives to make the shifts that are required" (p.18).

Chapter 3 makes a forecast of GNP for 1970 (\$870 billion). With the increases in tax revenues generated by our existing tax schedules, federal spending increases and/or tax reductions amounting to \$40 to \$45 billion over the next five years must occur if the economy is to remain at full employment.⁴

¹ U.S. Arms Control and Disarmament Agency, *Economic Impact of Disarmament*, 1962; and *The Economic and Social Consequences of Disarmament*, 1962, revised 1964.

² In general, political attitudes in the United States will not allow for the necessary government planning or authority to shift unemployed resources except in periods of crises. Thus the U.S. plan for partial disarmament, which was spread over a 12-year period to minimize adjustment problems, greatly reduced the possibility that the federal government would receive the necessary power to successfully combat the economic repercussions.

³ Added to the above-listed agencies, which were listed in the memorandum by the President establishing this committee, are the General Service Administration, the Small Business Administration, and the Office of Science and Technology.

⁴ Since most federal nondefense spending is for transfers rather than expenditures for goods

Assuming that defense outlays remain constant, nondefense spending (excluding interest) must increase by 70 to 80 per cent over the five-year period; or across-the-board tax cuts of 15 to 18 per cent must be made. (The 1964 tax cut was approximately a 10 per cent reduction in total federal revenues.) If a 25 per cent reduction in defense spending occurs by 1970, then the rise in non-defense outlays over five years must be 95 to 100 per cent or the reduction of all taxes must be 23 to 26 per cent. "If the very likely assumption is made that social security payroll taxes, customs duties, and miscellaneous (mainly non-tax) Federal receipts would not be subject to fiscal policy adjustments, the needed tax reduction would be equivalent to a cut of about one-third in all other Federal taxes" (p. 28).

The committee readily points out that macro-governmental programs such as tax reductions cannot prevent regional and industrial dislocations. "Without appropriate fiscal policies, however, not only will specific measures to solve distress be frustrated, but widespread national unemployment could result" (p. 29). The remaining three chapters (the unique part of this study compared to the earlier reports) are concerned with (a) the analysis of present governmental machinery being used to minimize the effects of economic dislocations, (b) recommendations for improving existing micro-governmental programs, and (c) the informational and research needs for strengthening micro-governmental programs. The criteria established for effective micro-programs are:

- (1) consistency with macro-policies promoting full employment and satisfactory growth;
- (2) consistency with standards of equity between sectors of the economy and regions of the country, e.g., special disarmament benefits should not be restricted to government employees but should be open to all employees;
- (3) consistency with the efficient allocation of the nation's resources;
- (4) consistency with local and private initiative;
- (5) consistency with national security needs.

The committee was impressed by the variety of governmental services that now exist. A basic problem is to coordinate these available services into an over-all program. Recommendations to assist in this necessary coordination are (a) the establishment of a Federal Task Force on Community Assistance to provide on-the-spot coordination in depressed areas, and (b) the establishment of a permanent committee, with a full-time staff, to expedite and give continuity to research outlined in this report.

The committee points out that the data are generally adequate in analyzing the impact of changing defense needs on the aggregate economy but are inadequate for studying regional and industrial dislocations. While reasonable estimates can be made on dollar magnitudes of prime contracts, the employment change of the prime contractor, and the amounts and employment impact of subcontracting are generally unknown. The time lags involved in the award-

and services, the same multiplier with different signs is used for expenditure increases and tax reductions.

ing of contracts and the resulting economic impact are also generally unknown. Research in these areas by the Department of Defense and ACDA is discussed as are the attempts to apply the latest input-output tables in determining industry impacts. Detailed studies are being made of South Bend, after the closing of the Studebaker plant; of Richland, Washington, after the closing of the A.E.C.'s atomic energy plant; of Seattle-Tacoma, after the reduction of Boeing's labor force; and after the closing of various military installations. The results of this research will greatly assist in understanding the problems of changing defense expenditures.

Although still overly optimistic in assuming that the economy can be made to perform satisfactorily if there is a significant amount of disarmament, this report has outlined many of the crucial problems which must be faced in such an adjustment. Even though the study is not as technical or as tightly organized as the professional economist might prefer, it does provide an up-to-date summary of the problems and of the efforts to solve these problems which are being made by the federal government.

ROBERT E. BERNEY

Arizona State University

Railroads and Regulation 1877-1916. By GABRIEL KOLKO. Princeton: Princeton University Press, 1965. Pp. vii, 273. \$5.00.

I consider myself lamentably well qualified to review this book. When it appeared I had already worked seven months during a sabbatical on a similar—nay, identical—project. After spending another month evaluating the book, I decided that there was little point to continuing with my own study. From this the reader may deduce that I have a high opinion of the volume, a presumption I shall proceed to verify.

Professor Kolko, an historian at the University of Pennsylvania, has set out to reinterpret the origins and early history of the Interstate Commerce Commission. He takes as orthodoxy the position that the ICC was established to engage in trade regulation of a monopolistic industry as a consequence of public revulsion to the industry's excesses. More specifically, he endeavors to refute the *locus classicus* of such views, I. L. Sharfman's compendious, but adulatory and uncritical history of the Commission.

Kolko demonstrates that the purpose of the Act of 1887 was simply to lend stability to railroad cartels which the expansion of the industry had rendered chronically unstable. Rail rates had fallen steadily throughout the post-Civil-War period so that it was their instability rather than their absolute level which was a source of widespread dissatisfaction. Merchants, farmers, and railroad managers alike found the characteristic pattern of alternation between collusive pricing and rate wars intolerable. Kolko in his discussion of the origins of the Act of 1887 is principally concerned with demonstrating political support by railroad management for establishment of a federal commission. Railroad magnates typically preferred Cullom's formulation of the Act of 1887 in the Senate, which included establishment of the ICC, to Reagan's

bill in the House, which provided for enforcement of published rates by recourse to the courts.

Kolko's history of the early behavior of the ICC is a devastating demonstration that the Commission looked upon itself as a cartelizing body from the outset. Cooley, the first chairman, had a solid background in arbitration of disputes within the railroad cartels. The Commission's early jurisprudence centered about acceptance of discriminatory pricing, putting down of rate wars, and encouragement of collusive rate making. The Commission's statutory authority for all this was grossly inadequate. It had no statutory power to set rates, and the Act of 1887 neglected to legalize the collusive activity it was designed to facilitate. Kolko interprets the Commission's early reverses in the courts not as interferences by a *laissez faire* oriented judiciary with a progressive regulatory body, but as inevitable consequences of the vagueness of the Act of 1887. The Acts of 1903, 1906, and 1910 he interprets as efforts to strengthen the Commission's original puny powers for cartelization. Kolko appears somewhat more at home in the period 1900-1910 than in the earlier years. His treatment of the Elkins Act of 1903, the most potent of the pre-1920 statutes in requiring adherence to collusively set rates, is particularly impressive. He demonstrates that the Act had its origins in the legal department of the Pennsylvania Railroad and was the product of railroad pressures throughout. By the eve of the first World War, The Commission was succeeding in the course on which it had been set in 1887: cartelizing the railroad industry without pooling.

Kolko's interpretation seems to me perfectly correct. It surprises me only that the academic community took until 1965 to produce a book which sees the ICC for what it was—and is. Being so familiar with the author's sources, I found the historical record so unambiguous that I have difficulty conceiving how a long line of scholars can have avoided the conclusions of this volume.

In spite of the book's general excellence and correctness, it will leave most economists unsatisfied in several respects. The author is almost exclusively devoted to demonstrating that railroad pressure was mainly responsible for the development of public policy. There is a strong implication that the policy was undesirable. I am convinced of it, but there is nothing in the book to provide one with a framework for reaching this conclusion. Kolko is writing about collusions, but he makes no use of the theory of cartels which he could easily have found in an intermediate or even elementary text in economics. I suspect that some explicit theoretical basis would have helped him pick up some major points that he missed. Notably, Section 5 of the Act of 1887, a prohibition on pooling inserted in a Senate-House reconciliation of the Cullom and Reagan bills, was inconsistent with the rest of the Act, which was almost entirely devoted to facilitating collusion. Similarly, Kolko fails to recognize that the practice of charging more for a short haul than for a long one was both a form of discrimination against areas without water transport and a means of rate-cutting to points at which the railroads were competitive with one another. Accordingly, his treatment of the differing texts of Section 4 of the Act of 1887 in the Reagan and Cullom bills and of the Commission's troubles with Section 4 in the Courts in the 1890's seems to me less perceptive

than it should be. Finally, Kolko's discussion of *Smyth v. Ames* (1898) is entirely inadequate. The ICC was not established to engage in public utility regulation in the usual sense of valuation and simulation of a competitive return for a monopolistic firm. Insofar as it behaved that way in its later history, it was largely because of the common law obligations placed on it by *Smyth v. Ames*. Kolko mentions the case only once, almost as an aside.

Withal, this volume represents a distinct advance in our knowledge of economic history. Let us hope that the book also prompts the intellectual community to see the Interstate Commerce Commission for the cartel that it is, and thus contributes toward its eventual elimination.

The Economics of Nuclear Power. By J. A. HASSON. London: Longmans, Green and Company, Ltd., 1965. Pp. vii, 160. 35s.

This book is more or less unique in the literature dealing with the economics of nuclear power. Most earlier works can be classified into one or more of the following categories: (a) quantitative projections of a specific country's (or a group of countries') energy consumption total and of the likely role of nuclear power within that total;¹ (b) economic analysis of the long-range effects of nuclear power on specific industries and/or regions via input cost reductions and/or changes in technology due to postulated energy costs (presumably) below costs from alternative sources of power or heat;² (c) discussion and analysis of the political economy of nuclear power, covering the economic effect of government policies toward the development of nuclear energy and of government regulation and/or operation of substantial components of the nuclear energy industry;³ (d) relatively more technical studies reviewing the current status and/or future prospects of nuclear costs and technology, including, as a major subcategory, nuclear fuels;⁴ (e) studies of the conceptual

problems involved in finding the cost of nuclear power;⁵ and (f) in addition, there are studies covering nonpower applications, such as desalting sea water, food preservation and other radiation applications, nuclear ship propulsion, isotopic power sources, etc.⁶

J. A. Hasson's book falls largely outside these categories. His primary concern is the application of some of the newest theoretical tools of economic analysis to the question of the economic costs associated with the development of nuclear power. His book is therefore more a discussion of these several tools against the background of nuclear energy than an analysis per se of its promises and problems. This distinction is essential if the reader wishes to avoid some serious misunderstanding.

In Chapter 1, Hasson devises a linear programming model of a nuclear energy "industry" (defined to include the entire vertical range of economic activities from mining uranium, through ore concentration, fuel fabrication, fabrication of special nuclear equipment, operation of the nuclear power plant and chemical reprocessing),⁷ and he elucidates the technological constraints on the system and the objective function to be optimized. He next presents a cost function of a nuclear power plant, and, in defining parameters and explaining formulas, takes advantage of the opportunity to review some of the technological relationships underlying nuclear energy. In Chapter 2 he considers the development of a nuclear power industry from the standpoint of welfare economics, and he devotes ten pages to an excursion into the topic of consumers' and producers' surplus as applied to nuclear power.

The next major topic of discussion (in Chapter 3) is the application of benefit-cost analyses to public investments in nuclear power development, first in the United States, then in the United Kingdom, and finally in India.

In his fourth and final chapter, entitled "Factors in the Choice among Alternatives," Hasson seeks to provide some perspective regarding energy problems in general, as well as in the several countries mentioned, and he reviews factors to be taken into account by an electric utility executive, or nationalized-power authority, in meeting future load growth in choosing between alternative types of generating capacity. The treatment is more descriptive than

⁵ International Atomic Energy Agency, Technical Reports Series No. 5, *Introduction to the Methods of Estimating Nuclear Power Generating Costs* (Vienna 1961); U.S. Atomic Energy Commission, *Guide to Nuclear Power Cost Evaluation*, TID-7025, Vols. 1-5, study by Kaiser Engineers (Washington 1962).

⁷ This list of nuclear activities omits uranium enrichment in diffusion plants, which constitutes a substantial cost component in any reactor system employing fuel enriched in uranium 235, as well as waste disposal, including storage, which under any reasonable projection of future nuclear capacity could loom large.

ological, in contrast to the preceding three chapters, and may contain information useful to the nonspecialist.

Except for some comments regarding the cost-benefit analyses, I have not tried to review the application of any of the analytical tools enumerated. Hasson demonstrates considerable mastery of these techniques and, as well as of the esoterica of consumers' and producers' surplus, and deserves to be praised for his imagination and ingenuity in seeking to apply these tools to the problems raised by nuclear energy. As suggested, this represents a significant and eminently worthwhile broadening of the subject matter covered by nuclear economics. In this connection, however, and as a very minor footnote, it must be observed that Hasson's style tends to misuse of mathematics—quite often perfectly simple and understandable statements are promptly restated as mathematical formulas (on several occasions correctly) and almost as promptly forgotten without any apparent rea-

occasion arises in formula (4.1), page 103—here the formula is in my opinion superfluous and, what is worse, misleading. The a_i terms should properly bear a second subscript to denote the particular region they refer to; a_i in region r differs from a_i in region s . Otherwise one might conclude that the only difference between $\Pi_1 = f_1(a_1, a_2, \dots, a_n)$ and $\Pi_{11} = f_{11}(a_1, a_2, \dots, a_n)$ is the functions f_1 and f_{11} applied to the same set of a_i values. A second example occurs in formula (4.3) on the following page; in this case there is a parenthesis missing around the term $(\Pi - \gamma)$ and the denominator λ is incorrectly defined; λ should be expressed in units of thousands of hours of operation per year corresponding to the desired plant output and not as a per cent, as stated. This is necessary in order to convert the expression $(\Pi - \gamma)/\lambda$, the denominator of which is given in units of Kwh, into units of KW, so as to be consistent with the other two terms in the numerator. A third instance occurs on page 107. In formula (4.5) the symbols γ and λ are used twice, each time with a different meaning; the first meaning has been given on page 16, and the second on page 107.

These are matters more of style than substance and need not detain us. The more serious shortcomings of this book are primarily concerned, as stated earlier, with the substantive aspects of energy in general and of nuclear energy in particular.

The most prominent deficiency centers around that fact that Hasson's information is hopelessly outdated. Most of his references to nuclear costs and to nuclear technology are to the late 1950's; rare indeed are references later than 1960 or 1961. Yet, in the period since then, the competitive prospects for nuclear power have been markedly altered. As late as November 1962, the *Wall Street Journal*, which has never been accused of pessimism in regard to nuclear prospects, was projecting 4 mill/Kwh costs in large nuclear power plants built only in 1975-80. Barely a year later, however, the famous Jersey Central announcement heralded the likely attainment of this low generating cost figure a decade sooner.⁸ Much of this speed-up has resulted from a drastic

A useful summary of the present status of nuclear costs and technology can be found

drop in the capital cost/KW of nuclear plants, down close to the capital cost of conventional plants, a development of enormous significance, both domestically and abroad, insofar as the future competition between nuclear and conventional plants is concerned. While it is recognized that it is extremely difficult for one person, in undertaking a work covering such a wide range of subject matter, to be completely up to date, I cannot believe that a book published in 1965 and hence, presumably, in manuscript form in, say, mid-1964 could not have been more recent. And in a field like nuclear energy, the technology of which is changing so rapidly, the nonspecialist who relies on Hasson's costs and technical parameters will be as out of touch with the current status as was Rip Van Winkle.⁹

Not only have the current status and near-term cost prospects of nuclear energy been dramatically altered, as indicated, but significant institutional factors have also been changed. It is surprising to read on page 24, ". . . in practice a 4 per cent carrying charge is levied [on the nuclear fuel inventory] by the A.E.C." when, in fact, this rate was raised to 4¾ per cent in July, 1961, an event which was widely discussed at the time in the trade journals and elsewhere. There is not even a footnote mentioning the change in a book published in 1965.¹⁰

It should be added for the benefit of the nonspecialist that the institutional framework within which nuclear fuel costs are determined has been further changed by the passage of legislation in August 1964 permitting (and after January 1, 1971, requiring) private ownership of nuclear fuels, thus ending the government ownership monopoly on all fissionable materials whereby nuclear fuel was leased to users at rates involving a subsidy.

Other examples, indicating what can only be termed unfamiliarity with nuclear "facts of life," both current and not-so-current, can also be cited. Lack of space prevents mentioning more than one of these. In Chapter 3, starting on page 70, Hasson presents a cost-benefit analysis of the U.S. Civilian Reactor Development Program. In deriving a base for comparison with generating costs in subsequent nuclear plants, in order to determine the benefit terms of his cost-benefit ratio, Hasson utilizes the well-publicized generating cost of the Shippingport plant (62 mills/Kwh), generally referred to as the first com-

in "Nuclear Power Economics—Analysis and Comments—1964," Joint Committee on Atomic Energy, 88th Congress, 2nd sess., October, 1964.

⁹The author was undoubtedly aware of this, since he stated the following in the Preface (p. viii): "While empirical analyses exist, events have moved and I do not assess whether or not time, increased knowledge and experience have treated these kindly. It is nevertheless anticipated that this work fulfills a useful purpose."

The question here is whether the nonspecialist in nuclear matters is enlightened or misled by the use of obsolete costs and parameters. If the data are wrong—or at least no longer valid as Hasson admits—and if the task of incorporating more up-to-date and relevant data is in fact insuperable, perhaps it would have been preferable to use entirely hypothetical data so to avoid this danger.

¹⁰In another context, Hasson does refer to the AEC schedule of charges for enriched uranium which was also changed on the same date (p. 74, footnote 2).

ized nuclear power plant in the United States. He thus secures a gross differential between the 62 mill figure at Shippingport, completed and the 11.1 mill figure at the Yankee plant, completed three years though this is described as "recently" in the book). But this is a gross retortion of the Shippingport figure, which includes the considerable innumerable test facilities, extra loops and instrumentation, etc., built for research purposes. It is more correct to characterize the Shippingport as a laboratory operated primarily for information, and producing electricity as a by-product, than to consider it a nuclear power plant in any sense.¹¹ To attribute all the Shippingport costs to power generation in analysis betrays a considerable naïveté regarding nuclear matters. My earlier blanket endorsement of the analytical tools used by Hasson at this point make one comment regarding the application of cost-analysis to nuclear power development. On page 76 Hasson states:

Assessing nuclear power, benefit-cost ratios can be calculated at three levels: (1) for individual plants; (2) for reactor concepts; finally, (3) for the entire nuclear power industry. Assessment at the two levels entails accounting for indirect effects which involve indirect economies, transferable know-how, and other kinds of interdependencies.

Cost-benefit analysis is concerned with the individual plants and not with "immediate" or direct benefits. And despite the statement quoted Hasson goes on to say (p. 79):

Ranking of reactors with a benefit-cost ratio less than one would be altered if allowances for indirect gain—external economies; transferable know-how, etc.—were made. In any case, evaluation of indirect benefits from investment in individual reactor concepts is complicated; it is difficult to determine what benefits will be received, and what benefits will be imparted to other projects.¹

It will take the form of reduced capital costs, higher fuel exposure levels, changes in fuel take-up, improvements in fuel fabrication, chemical reprocessing, etc. Accounting for indirect dependence may occur only through side calculations not an integral part of the benefit-cost ratio. Careful empirical study would be essential.

It is not clear from these two quotations whether Hasson believes indirect benefits should or should not be included, if data were available, in the particular benefit analyses under discussion. It is my belief that they are indispensable, since, as Hasson admits later on the same page, all of the plants included in the analysis are of a predominantly prototype nature. Their main purpose is for the gain in knowledge to be secured—knowledge not re-

From the *Atomic Energy Desk Book*, by J. F. Hogerton (New York 1963), the Shippingport reactor is described in the following terms: "Its main importance, however, is as a research and development facility. . . . It was designed and is equipped to test new designs and explore operating variables as well as to obtain experience in the development of nuclear power generating. It is much more heavily instrumented and has more operating flexibility than any other U.S. power reactor of comparable size" (p. 500).

stricted in applicability to that particular type of reactor technology—whereas the actual generating costs of each and their comparison with Shippingport as a base, which forms the sole component of the benefits term, is of a distinctly secondary importance.

I would also question Hasson's assertion, in the first sentence of the second paragraph quoted, that the ranking of reactors would be unaltered if allowance were made for indirect gains, since these indirect benefits will differ among themselves. Hasson's bland assertion is unsupported by any visible evidence, and it is not clear to me whether it is intended merely as a mathematically correct assertion deriving from the theory of cost-benefit analysis or whether it rests on an empirical evaluation based on rough estimates over the reasonable ranges of the relevant indirect benefits.

My final comment concerns Chapter 4, which is a hodgepodge of empirical information concerning installed generating capacity in West Germany and coal transport costs in West Germany and India, of commonplace generalizations regarding fuel competition and factors determining the growth of electric power demand, and of mathematical formulas intended to accord these generalizations a symbolic dignity. All of these factors, identified as being relevant in extending electric power capacity, reduce essentially to short-run and narrowly defined cost comparisons, such as might be faced by a private electric utility in the United States. There is therefore no connection between this chapter and the three preceding, and none is attempted, even when the author discusses the case of nationalized electric authorities, such as those in India or the United Kingdom, which should properly and do concern themselves with the questions raised and the conclusions of the preceding discussions regarding nuclear power development.

It is difficult to summarize my impressions regarding this book. It is a welcome attempt to apply sophisticated analytical tools and concepts to an admittedly complex and rapidly evolving technology, and the author's failure to master the technological part of this job does not detract from the fact that he was the first with sufficient courage to undertake the task. Having guided a research and development effort which by now has essentially achieved competitive nuclear power in low conversion ratio reactors of large size, the AEC is now pressing forward at an annual rate of well over \$200 million to develop advanced converters and to master breeder reactors. Mastery of the breeders is expected during the 1980's, with advanced converters available at an earlier date. The ostensible justification for this effort is that only breeding will permit us to make efficient use of our fissionable fuel resources, and so avert an alleged, but questionable, shortage of conventional fossil fuels one or two centuries hence. No one has tried to test the economics of this effort, and Hasson's effort will be useful when and if this is ever undertaken.

PERRY D. TEITELBAUM

Resources for the Future, Inc.

Land Economics; Agricultural Economics; Economic Geography; Housing

Economic Crises in World Agriculture. By THEODORE W. SCHULTZ. Ann Arbor: University of Michigan Press, 1965. Pp. viii, 114. \$3.50.

Soviet Agriculture: The Permanent Crisis. Edited by ROY D. LAIRD and EDWARD L. COWLEY. New York: Frederick A. Praeger for the Institute for the Study of the USSR, in cooperation with the University of Kansas, 1965. Pp. xii, 209. \$7.00.

The title of these two volumes suggests that a new and major crisis has developed recently in the world agricultural situation. In fact, of course, almost the opposite is true in that most of the world's agriculture is operating much as it has in the past, despite technical aid, central planning, and numerous other social, political, and economic schemes to change it.

Essentially, Theodore Schultz's book is an examination of why farmers in most countries have changed so little, given the observable fact that major increases in agricultural productivity have been achieved in a few nations. For those familiar with Schultz's recent *Transforming Traditional Agriculture* the present book contains little that is new, although one has a feeling that he has somewhat expanded his horizons to take into account some of the criticisms of his earlier volume. Since this present volume was a series of lectures it is somewhat shorter and more general and omits the case documentation of the other work.

The Schultz reasoning is as follows: Traditional agriculture is well organized around the resources available to it. Productivity is low because there is little economic incentive to add more of the conventional inputs that are available. Incentive is lacking because the available inputs offer low returns, the system is organized to provide insufficient incentives to farmers, or the farmers are incapable of utilizing the complex inputs necessary in modern agriculture. Schultz argues that in the poor countries agricultural productivity can only be increased by providing new inputs that will provide farmers with higher rates of returns for investment in agriculture and by advancing the level of education of farmers. He puts relatively less emphasis upon the social and economic organization of underdeveloped areas and the barriers these provide to the expansion of output. Even so, he gives such matters more concern in passing than previously. However, in discussing the problems of Russian agriculture he puts all of the burden of unsatisfactory performance upon the system of organization and does not discuss the nature of the inputs available to Russian agriculture and their potential productivity.

The volume *Soviet Agriculture: The Permanent Crisis* is a more detailed examination of the same question posed by Schultz. Why has Soviet agriculture failed to perform better? The book consists of papers given by outside experts of Russian economics and politics. Some of the papers measure the performance of Russian agriculture, some of them compare its performance with

other areas of the world, and others examine the Russian agricultural system and recent changes in it.

To one who claims no expertise in matters relating to the Russian economy, including agriculture, the book is somewhat frustrating, as is often the case of material prepared by and for a highly specialized group of experts. For an outsider it tells both too little and too much. It tells too little about the general situation, which any Russian expert would know; and it tells too much about things which to the nonexpert would appear to be details which may obscure rather than illuminate these general issues. However, to the specialist in Russian affairs these may well be strengths rather than weaknesses.

The conclusion of this book would appear to be that the system of organization is the reason for the failure of Russian agriculture. In a broad sense this is undoubtedly true, but the question that remains is what specific parts of the system? What is the level of technology available to Russian agriculture and the quality of inputs in terms of their potential productivity? What is the level of education and technical competence at the different levels of decision making? How important is the transportation and distribution system for inputs and output in determining the usable agricultural output produced in Russia? How important is the complex delivery and pricing system in providing incentives for increased output? These are the questions Schultz is mainly concerned with in the world scene because he believes them to be major variables in explaining the differential performance of agriculture. Few of these questions are directly addressed in *Soviet Agriculture: The Permanent Crisis*, and even fewer are answered.

While the book on Soviet agriculture answers too few of these questions, it seems that Schultz may answer too many, too assuredly in his *Economic Crises in World Agriculture*. For instance, he asserts that our surplus disposal program to underdeveloped countries is an important contribution to the poor performance of agriculture in some countries via the program's price-depressing effects in the recipient country. No firm evidence is given for this position, nor do I know of any available elsewhere. A similar problem exists regarding his assertion that there are almost no inputs or techniques available to farmers in underdeveloped areas which would be profitable for producers to adopt. This is not to imply that Schultz is wrong in his assessment of economic conditions in world agriculture, but merely to suggest that substantially more specific economic information on these issues is needed.

In general, both of these books are addressed to the important question of the reasons for the varying performance of world agriculture. Both point a finger at one or more general factors that appear to be the root of the problem. Both deal with questions of fact which are subject to some differences in interpretation. For those persons concerned with improving the performance of agriculture, either as teachers, researchers, or policy-makers these books would appear to be useful inputs which ought to help increase the productivity of their efforts. Despite these improved inputs, much clearly remains to be done.

The Economic Demand for Irrigated Acreage—New Methodology and Some Preliminary Projections, 1954-1980. By VERNON W. RUTTAN. Baltimore: Johns Hopkins Press for Resources for the Future, 1965. Pp. xi, 139. \$4.00.

Concern about natural resource adequacy for the future has led to a substantial professional effort to project or predict future requirements. Economists have agreed to the making of many such projections. There has been no particular reason that economists should have engaged in such activity because most of the contribution that their discipline could make in such work has been ruled out by assumption. In this study Vernon Ruttan attempts to do something about this state of affairs. It is heartening that Resources for the Future has supported his work. Despite the trenchant economic analyses that RFF-supported economists have made of past developments and contemporary government programs and agencies, their record in utilizing economics in projecting future "requirements" has not been as bright.

The book is a scholarly one and represents an advance in methodology. At the same time, the empirical findings should not be disregarded even though Ruttan is conservative in his interpretation of the results. This reviewer is willing to predict that Ruttan's work will have an indelible impact on future projection studies.

The technique was to estimate Cobb-Douglas regional production functions for agricultural production by the use of census data. Three models were developed: a productivity model, a demand model, and an equilibrium model. The productivity model is of a simple form with the value of farm products sold being a function of irrigated land and operating expenses. From this a marginal-value productivity function for irrigated land could be obtained. The demand model permitted the derivation of a demand function for irrigated land in each region. Given the specified level of output in each region and the equation for the production function, the model was solved to obtain the number of acres of irrigated land in each region which equates the annual marginal-value productivity of irrigated land with a specified annual return per acre of irrigated land. The equilibrium model consisted of three equations. One was the Cobb-Douglas production function mentioned earlier. Another was MVP functions for irrigated land and operating expenses for each region. The third was two identities equating the calculated MVP levels with budgeted average-cost levels.

The empirical results are interesting to anyone concerned with water resources policy. Space limitations prevent a thorough review here. Suffice it to say that the models bring into serious question the economic feasibility of much irrigation in the West under current conditions. Ruttan makes projections to 1980 using the demand model and the equilibrium models. These projections are then compared with estimates made by the Departments of Agriculture and Interior in their requirements approach. Ruttan's projections are more consistent with those of the Department of Agriculture than they are with those of the Department of Interior. They also suggest that agencies may be overestimating irrigation potential in the West and are underestimating it in the East. This reviewer would feel more comfortable with the results if he

knew more about some of the empirical data. For example, the costs per acre have considerable effect on the equilibrium solution. If these costs are not accurate in future estimates, the resulting equilibrium solutions would also be in error.

In making his projections Ruttan does not become a captive of his models. When the results appear "unrealistic," he examines the situation carefully to discover "why." He then introduces restraints to correct that which was incomplete in the original model. Although some may be critical of the admittedly arbitrary procedure, Ruttan makes the valid point that his projections "contain fewer arbitrary elements and are much more sensible from an economic point of view than many requirements projections upon which important decisions have been based."

Ruttan is justifiably cautious in arriving at his policy conclusions. The principal ones appear to be:

1. There is little, if any, economic justification in terms of meeting food and fiber needs of the next several decades in investing in irrigation facilities in which total costs are less than total returns on the basis of current prices.
2. Subsidizing a factor input such as irrigation water is a relatively inefficient form of income redistribution.
3. Federal policy with regard to irrigation in the West should be re-examined.
4. A substantial growth in irrigation may be economically practicable in eastern water resource regions.

In the opinion of this reviewer, the major contribution of the work is the methodological achievement of permitting economic forces to play a role in the making of projections. Ruttan is well aware that he has only opened the door a crack. Nevertheless, it may be the more important variables that have been admitted. Even if they have not, Ruttan has moved in the right direction. Should we wish to move farther in this direction, a more sophisticated basis than the rather elementary Cobb-Douglas production function will undoubtedly be needed. Nevertheless, a start has been made.

EMERY N. CASTLE

Oregon State University

The Economics of Subsistence Agriculture. By COLIN CLARK AND MARGARET HASWELL. New York: St. Martin's Press; London: Macmillan & Co., 1964. Pp. x, 218. \$6.00; 30s.

"Subsistence agriculture" is a kind of catchall term. We come across it frequently these days, applied loosely to practically every kind of agricultural production not directly aimed at the market. Sometimes the unit of "subsistence agriculture" is the individual family, sometimes a village, sometimes a region, sometimes a whole rural sector, sometimes a whole country.

Colin Clark and Margaret Haswell had a splendid opportunity to introduce some order into this jumble-shop. They might have staked out the limits which separate subsistence agriculture from other kinds of farm economy.

They might have specified the level of analysis. They might have tried their hands at sketching the over-all functioning of subsistence agriculture as delimited and defined. Far from attempting any of these tasks, the authors have not even told us what they mean by subsistence agriculture.

The book begins with a rehash of the senior author's running controversy with the FAO about how hungry or ill-fed the world is today. This clash has previously been published, notably in the pages of the *Journal of the Royal Statistical Society* in 1961 and 1962 and again as part of the volume entitled *Food Supplies and Population Growth* (Edinburgh and London, 1963).

The FAO side of the controversy is by far more popular these days. The FAO tells us that between one-third and one-half of the world's population are hungry or malnourished, and that, with the upswing in population, things are likely to get much worse unless there is a sustained drive for a great increase in food production. It seems churlish to challenge this, particularly if one is living in one of the better-fed countries.

Far from being afraid of appearing churlish, Clark seems positively to enjoy it. He contends that a much smaller minority of the world's population, perhaps as low as 10 per cent, are really "hungry." A much larger percentage, perhaps 30 to 40 per cent, may be living on a poor and monotonous diet, but they are getting by.

My own feeling is that the issue between the FAO and Clark has not been properly posed. Both sides seem to exclude the possibility that people can eat more and, subjectively, feel hungrier. Yet this is precisely what I suspect has been happening in the one large area on which I feel qualified to speak, India. In the past 15 years the trend increase in food output has been of the order of 3 per cent per year, whereas the trend increase in population has been 2.5 per cent per year. Although more food has been available and ordinary people, until the recent steep price rise, have been eating more food and better food, nonetheless they will tell you in the villages that they are worse off. The fact is that their standards and levels of living have both risen, and that they are no longer content to accept the inadequate diet of the preceding generation.

After their presentation of the earlier controversy with the FAO, our authors take up a series of such topics as level of agricultural output, utilization of labor, man-land ratios, productivity, rents and prices of land, role of trade in relation to different methods of transport, and aid and development policies. Any and all of these topics are worth discussion, but the way the authors have gone about it is disconcerting. Their chief concern seems to have been to heap up mounds of quantitative data at any level (national, regional, village, or family) and of any quality. The material is drawn from all periods of history: ancient, medieval, or modern; from all continents; from all kinds of disparate inquiries—answers to oral and written questionnaires prepared by present-day economists, sociologists, or anthropologists, budget investigations of the 19th or 20th centuries, agricultural department data, statistical yearbooks. Perhaps since Africa is the continent about which I know the least, the data for that area seem to me the least objectionable!

When Clark's *Conditions of Economic Progress* first appeared in 1940, it was a pioneer, valuable, and exciting contribution. Nonetheless, the way in

which he threw together heterogeneous data to make tables, charts, scatter diagrams, functions and regressions was often and severely criticized, not least of all by Simon Kuznets in 1941. But Clark is irrepressible. Together with M. R. Haswell he has put together in *The Economics of Subsistence Agriculture* a series of 60 odd charts and tables which are open to the same basic objections as those in his *Conditions of Economic Progress*, while the text has none of the redeeming qualities or the interest of the earlier work. Prospective readers of *The Economics of Subsistence Agriculture* should look with a wary eye, for example, at the diagrams of average and marginal returns of agriculture, the treatment of rents and prices of agricultural land, the presentation of "preferred [*sic*] amount of agricultural work by Indian farm families," and the figures for income elasticities of demand for food and nonfood products in various eras and countries.

To a significant extent the haphazard character of the statistical materials purveyed by Clark and Haswell reflects their failure to define the nature, time-range, and coverage of subsistence agriculture. This vagueness means that they have no explicit criteria for judging what data are relevant or irrelevant. So long as the term subsistence agriculture remains a residual category, the present reviewer is inclined to feel that other researchers may be no more successful with it than Clark and Haswell have been. Perhaps the first thing to do now is to chop the term up.

DANIEL THORNER

Sorbonne, Paris

Labor Economics

The Emergence of an Industrial Labor Force in India—A Study of the Bombay Cotton Mills, 1854-1947. By MORRIS DAVID MORRIS. Berkeley and Los Angeles: University of California Press, 1965. Pp. 263. \$7.50.

Professor Morris seeks to describe and explain "the creation of an industrial labor force." He selected one of the most important work forces in an underdeveloped area: the 200,000 cotton textile workers of Bombay City. The historical resources for such a study are rich. The book is largely based on a scrutiny of various government labor investigations and testimony presented thereto, the official written records of the Bombay Millowners Association and various individual mills, and on contemporary articles published in trade and professional journals. Unfortunately, the study stops at India's year of independence, 1947.

Two quite different (and sometimes incompatible) strains are incorporated: (1) this is an economic history of the Bombay cotton textile work force; and (2) it is a polemic against what Morris regards as an erroneous view of the nature of the Bombay cotton textile worker. Let us consider each of these in turn.

The book contains a provocative, albeit too brief, history of the Bombay cotton textile industry, a comprehensive analysis of the supply of labor, a brief history of the hours of work, a penetrating historical sketch of work reg-

ulations and the administration of the work force, a thoughtful investigation of the relation between wages, trade unions, and labor discipline, and an excellent bibliography.

We have little that can match the quality of this book on the economic history of the American labor force, let alone that for an underdeveloped country. Morris worked on this topic for over ten years, and the product fully reflects the painstaking effort expended. We need more such studies on the emergence of a labor force in the course of economic development.

This book is also a polemic. And he treats his predecessors roughly. Interwoven in his analysis is a systematic effort to destroy what he regards as certain well-established "myths" about the Bombay cotton textile labor force. It has been assumed by many writers (but not all) that the Bombay cotton worker was not fully "committed" to an industrial way of life. This has allegedly been reflected in high absenteeism, labor shortage, high labor turnover, low mobility between mills, and the existence of a "village nexus" which drove workers to return to their villages for extended periods each year.

Morris' study constitutes a broad scale attack on the above description of the Bombay cotton worker. This attack on the traditional view of the worker's instability seems well taken and is a valuable antidote to much that has been written. However, he probably overstates his case. He argues that absenteeism among Bombay cotton textile workers has actually been relatively low—probably never more than 10 per cent, and that illness, not lack of commitment to factory life, accounted for most of this. He concludes that with the exception of the plague years of 1896-98 the industry has never experienced a "labor shortage." He maintains that labor turnover was probably never high. Attachment to the individual mill greatly increased over time, and, as I have shown for the period since 1947, extremely low turnover is currently characteristic of the industry.

He appropriately emphasizes that until recently the jobber played the crucial role in hiring and firing and that workers often needed an attachment to a jobber to obtain employment. Yet, he strongly implies that a good deal of inter-mill movement occurred. These two contentions strike me as inconsistent. His excellent historical description of the jobber system in Chapter 8 suggests a much more compartmentalized labor supply (in keeping with the view of other writers) than he describes in Chapters 4 or 5, and assumes in Chapter 9.

Concerning the "village nexus" thesis, he presents scattered data suggesting that a substantial minority have not been returning to their villages each year. However, his evidence indicates a majority did, and my impression is that they still do.

The loose discipline and low level of labor utilization which Morris appropriately describes may contradict his contention that this has been a well-attached labor force. Certainly, it is possible that employers permitted such poor control over their workers because they were afraid they would be unable to hold them otherwise. Morris argues that because wages were low and represented a low percentage of total cost, labor productivity could be neglected, that the important thing was machine productivity and "the critical object

was to guarantee the continued operation of the [high cost] machines." This argument fails to allow for the fact that in cotton textiles loose labor discipline almost inevitably leads to idle machinery.

Morris' basic conclusion is that the disciplining and commitment of the Bombay cotton textile labor force did not pose a great problem. He argues that this has also probably been true of developing labor forces in general.

He presents his case well. We now need a first-rate current labor market study of the Bombay cotton textile workers. This will not only tell us about the present, but will also shed light on the validity of what Morris tells us about the past.

RALPH C. JAMES

University of California, Davis

The Market for College Teachers—An Economic Analysis of Career Patterns Among Southeastern Social Scientists. By DAVID G. BROWN. Chapel Hill: University of North Carolina Press, 1965. Pp. xv, 301. \$7.50.

It is curious how few of us are willing to employ the equipment of economics to analyze the workings of our own profession and of the rather curious market for its services. How often we are content to direct our activities in that market on the basis of pure judgment, intuition, and perhaps some crude estimates of what constitutes a just price. Our economic training seems to have provided us relatively little insight into the subject—perhaps even less than most businessmen have into the operations of the markets in which they are involved.

Professor Brown has undertaken to increase our understanding of the academic market. While other books have been written on the subject, his is one of the few to be written by an economist and to be addressed primarily to his professional colleagues. The book adopts a supply-demand framework and deals with such important subjects as the cost and availability of information, impediments to mobility, and the objectives of those who seek jobs and of those who have positions to fill.

The bulk of the information on which the analysis is based was obtained from interviews. The sample was drawn from among economists, sociologists, and historians at 18 of the largest southeastern educational institutions; altogether 103 faculty members and 50 department chairmen were interviewed. To avoid problems arising out of faulty memory or inexperience with current market conditions the faculty respondents were all chosen among persons appointed since 1951, and most of them had taken their present post much more recently. Brown was well aware of the dangers inherent in the interview method and employed a questionnaire carefully designed to avoid at least the most obvious pitfalls.

The most interesting information that emerges from the study relates to the imperfections that characterize the market for our professional services—particularly the incompleteness of the information that is available to the typical buyer and seller. The author develops an admittedly crude but serviceable "Ig-

norance Index" for the job candidates, utilizing six questions such as "Did you visit the campus?" and "Did you know if other candidates were being seriously considered?" The index reports the proportion of questions answered negatively. The median index value was .24. The median candidate was uninformed on nearly a quarter of the questions at the time of his appointment. A similar index for chairmen indicates that their information was even more incomplete at the time the appointment was made. Brown argues that knowledge is so poor because the marginal cost of further information is so high and points out that where tenure appointments were involved information was generally far more complete. He recognizes that, particularly on first appointments, full information is very difficult to obtain—the institution from which the candidate comes is rarely candid, and he is usually not known by others in the profession.

The academic market's imperfection is also increased by its "balkanization." Though geographic impediments are less important for academics than for many other occupations, there are other bases for separation of our markets. Those who teach in church-related institutions tend to constitute a group that competes little with public liberal arts colleges; these in turn compete only slightly with the universities. More important, colleges and universities are segmented by quality of institution, and the institutions with considerable prestige do not participate to a great extent in the same markets as those with poorer reputations. Indeed, the author points out that only the institutions in the upper echelons operate in a truly national market, drawing their faculty members from schools of comparable reputation. Schools that are less well known are much more likely to draw their faculties from a narrower region.

Brown also concludes from his data that in selecting jobs, once a given salary level is met, faculty members are less interested in further salary differentiation than in other matters. While most respondents said they would be unwilling to accept a position that did not meet their annual salary requirement, more said that they chose their present position on the basis of reputation of the department and workload. Moreover, Brown concludes from questions based on published AAUP figures that the faculty members did not even know much about general salary levels at their own institutions (though this question may have been unfair in expecting them to have performed rather complex calculations with the AAUP data and to have remembered the results).

Brown's work is weakest when he turns to pure theory. His vague accusation that "since Adam Smith, respectable economic theory has held that wage and salary differentials are the primary forces acting upon the distribution of human resources" (p. 223) is surely unfounded, as a cursory reading of *The Wealth of Nations* would show. (See esp. Book 1, Ch. 10, Part 1.) To our knowledge theorists generally affirm that the wage is only part of the package that determines the attractiveness of a job. Similarly, his implication that an optimal allocation of resources requires us to know how to evaluate socially the social benefits of alternative uses of resources (pp. 260-61) seems to miss the point of the invisible-hand argument. But these matters do not constitute

the core of the book which, on the whole, is an illuminating and clear depiction of many of the characteristics of the highly imperfect market for professional services.

Population; Welfare Programs; Consumer Economics

Report of the Commission on the Cost of Medical Care, Vol. 1. Chicago: American Medical Association, 1964. Pp. 182. No charge.

The Economics of Health. By HERBERT E. KLARMAN. New York: Columbia University Press, 1965. Pp. 200. \$3.95.

The Demand for Hospital Facilities. By GERALD D. ROSENTHAL. Hospital Monograph Series, No. 14. Chicago: American Hospital Association, 1964. Pp. viii, 101. \$3.00.

The first sentence of the introduction to the AMA's report of the Commission on the Costs of Medical Care is: "The physicians of America are the primary members of a health team which provides the highest quality medical care in the world." This leads to the expectation, which is unfulfilled, that evidence will be presented to support this contention. No effort is made either to present evidence that is relevant for evaluating the truth content of this assertion or to discuss what evidence could conceivably demonstrate the truth or falsity of this assertion. Hence as it stands, it constitutes a self-serving propagandistic effort by the financial sponsors of this volume.

Nevertheless, this volume is not without appeal for economists. It contains three chapters of interest: (1) "The Economics of Medical Care," dealing with the structure of the medical care market; (2) "The Medical Care Price Index," concerned with the measurement of the medical component of the Consumers Price Index; and (3) "The Demand for Medical Care," which is a statistical study of the variables related to various classes of medical care expenditures. Only the author of the third of these chapters, Paul J. Feldstein, is identified. An impressive list of consultants, which includes many economists, appears in the Preface.

The chapter on the economics of medical care is interesting because of what it does and does not contain. It primarily consists of a set of data that shows how medical care expenditures vary with income, race, medical insurance, sex, education, time, GNP, disposable income, etc. Another set of figures shows how the number of physicians, nurses, and dentists varies as a fraction of the total population, along with a breakdown of physicians in practice by specialty. Associated with these data are some elementary lessons in economics with applications to the medical care industry. These lessons often confuse demand and supply schedules with points on these schedules. Adding to the confusion generated thereby are statements such as: "Supply is a function of demand."

The unknown author or authors assert: "The medical care industry has as its prime social goal the development and maintenance of optimum health levels," and a physician, if he is to succeed, will "... subordinate his personal interests to those of his patients." No data on the income of physicians are presented that reveal the financial sacrifices associated with holding these lofty ideals.

The chapter dealing with the medical care price index takes up a problem that the Price Statistics Committee of the National Bureau of Economic Research considered more broadly and comes to roughly the same conclusions. The medical care component of the Consumers Price Index measures, with some exceptions such as obstetrical care, the prices of medical inputs instead of the conceptually correct prices of output, which are more difficult to measure. In a society characterized by rising real per capita incomes, one would expect input prices of products embodying large components of human capital to rise in a regime of stable final product prices. Unfortunately medical care is often not sold on a per ailment or per complaint basis but in terms of inputs. Consequently inputs typically are measured and the changes in the productivity of these inputs over time in treating specific ailments are not captured in the medical component of the Consumers Price Index. This suggests that this index is biased in its measurements of the changes in the costs of medical care; over time it overstates the rise in medical care prices. Yet if one compares the change over time in the obstetrical costs of having a baby and visits to a physician's office, these price changes are almost the same.

The analysis of the trends in medical care relative to other prices leaves something to be desired. "Thus, it has been only in the past 11 years that medical care prices have increased at a faster pace than All Items. This has occurred, however, not because medical care prices have been increasing at a faster rate than they had previously, but because the increase of other prices has moderated considerably." This is surely wrong. The author is implicitly contending that if the previous rate of change of All Items had been maintained in the past 11 years, the rate of change of the medical care index would remain unchanged. Presumably the relative rise in the cost of medical care is independent of changes in the level of the All Items index.

Probably the most interesting of the three papers, and of all of the works under review, is the statistical study by Paul Feldstein. Feldstein, using cross-section data, attempts to analyze the influence of tastes, income, and relative prices upon the demand for hospital care, physician services, drugs, and dental services. He is most successful in isolating the influence of income upon the quantities demanded, and clearly shows that the demand for medical care is income-elastic. To isolate the effects of tastes, he utilizes variables that are less than perfect indicators of tastes, such as age of family head, per cent of families with one or more members 65 and over, per cent of families with one or more members under five years of age, urbanization, marital status, and education. Income is more successfully isolated than tastes; should education increase or decrease expenditures for medical services? Feldstein's results show a decrease. It is with respect to price elasticity that Feldstein's results are especially interesting and noteworthy. Clearly most forms of medical in-

insurance reduce the private marginal costs of medical care. Hence, the quantities utilized should increase; Feldstein's results show that they in fact do increase and are relatively more important for hospital expenditures than they are for physician expenditures. He also estimates price elasticity by looking at the relationship between average expenditures per physician visit for each of his primary sampling units, and the number of physician visits. He finds a weak negative relationship and interprets this finding as evidence of an inelastic demand. Possibly this is right if patient visits can be regarded as a homogeneous commodity. If they cannot, then one would suspect that variations in expenditures for physician visits are associated with variations in the quality of the services provided. Feldstein has shown that the market substitutes more frequent visits to low-quality doctors for less frequent visits to high-quality physicians.

Herbert Klarman's study, which is sponsored by the Ford Foundation and carries an introduction by Marshall Robinson, tries to "... engage the interests of economists in the problems of the health field," and "... acquaint the intelligent lay public and professional health personnel with the approaches, analytical methods, and viewpoints that economists bring to the health field. . . ." The volume consists of a survey, often very uncritical, of the literature in the field of health economics. Preceding each chapter is a little lesson in economics which makes no contribution to the subsequent discussion and upon occasion is incorrect as in the case of demand when Klarman describes the prices of goods other than the good under investigation as being given.

In his chapter on demand, Klarman rejects the notion that the discriminating monopoly model is appropriate for analyzing the pricing behavior for doctors. The rationale for this position is that the demand curve for physicians' services is inelastic. The principal piece of evidence available for this assertion is the Feldstein study which assumes, erroneously, that differences in the costs of visits to physicians are not equalizing differences, i.e., that visits to physicians are homogeneous among his primary sampling units.

Another interesting problem Klarman discusses is the relatively high medical and dental expenditures of those who carry medical insurance as compared with the uninsured. He concludes that the purchasers of insurance have stronger tastes for medical insurance: "The insured spend more than the uninsured because they want to . . ." but then goes on to say that there is little reason to believe that there is adverse selection of risks for insurance carriers. It is difficult to see how both of these positions can be accepted unless adverse selection refers to something other than economic costs for insurers. Surely those with strong tastes for medical expenditures must find medical insurance especially attractive, even if it has no impact on their consumption of medical services. Medical insurance seems to be a proxy for strong tastes for medical services; this is a point that Feldstein failed to consider in his analysis.

Klarman deals with the question of the appropriate level of state intervention in private choices for medical care by citing various positions taken by writers in the area from Seymour Harris to Dennis Lees but never taking a position of his own or attempting to integrate disparate views.

Klarman's chapter on supply is preceded by a little lesson in the economics of cost and supply curves which is totally irrelevant for the discussion of the output of physicians if, as many believe, output is controlled by the AMA. Under these circumstances, what is relevant is the AMA physician output policy which will be geared to the demand conditions for medical services. This chapter contains almost no discussion of the control over medical schools by organized medicine, which is an important distinguishing characteristic of this profession and is highly relevant for understanding what determines the output of physicians.

Also pertinent, but not discussed, is the role of standards of medical education upon the costs of medical care. Many mistakenly agree that any increase in the quality and rigor of medical training is desirable, forgetting the impact of such a change upon the prices of physician services. Insofar as prices of physician services rise, the public is induced to substitute the services of chiropractors, faith healers, and self-treatment for physician services. Hence an increase in the standards of training and costs does not imply an increase in the standards of medical care for the population at large. Klarman notes that the Russians have a higher frequency, approximately 30 per cent more, of physicians per unit of population. Since these physicians are on average of lower quality than ours, the Russians have implicitly substituted quantity for quality.

In his discussion of physician incomes, Klarman takes up the question of whether the incomes of physicians are underreported. Those who contend they are underreported cite the existence of vacancies in health departments, and in HIP in New York, that carry salaries equal to or greater than the means reported by the Department of Commerce. Klarman counters this argument with the statement that doctors prefer not to undertake administrative work or be salaried and prefer solo practice. This is an incorrect argument: What is relevant is what's true at the margin; are there no doctors among the more than two hundred thousand in solo practice who do not have these tastes? Surely there must be a variety of tastes about these matters in the profession, and since a miniscule fraction are either salaried, doing administrative work, or both, one finds this argument difficult to accept.

One of the ideas that recurs in the literature of medical economics, and is reported by Klarman, is that the intensity with which hospital beds are used is independent of their frequency in the population. The reason for this phenomenon is not discussed by Klarman and the reader is left guessing as to the rationale for its existence. Such a rationale could be nonprice rationing of bed space. If there are unsatisfied buyers, an increase in the frequency of hospital beds per unit of population could be associated with no change in the intensity of their use. This is one of the questions Gerald Rosenthal's study of the demand for general hospital facilities seeks to answer. Unfortunately, this statistical study of the demand for general hospital facilities suffers from some shortcomings that raise serious questions about the validity of its findings.

The most useful variable that most investigators have found in studying the demand for medical care is income. This is typically the cornerstone of any

demand study in this field or in the field of consumption generally. Rosenthal's treatment of this variable is difficult to understand, given what has become common knowledge in recent years. He considers two categories of income, under two thousand, and six thousand and over. Such a procedure, looking at the extremes of the income distribution, will maximize the effects of transitory income and mask the very effects he seeks to uncover. This is by far the most important shortcoming of this very ambitious study. Rosenthal implicitly assumes that all charges for hospital beds measure the same thing. Hence all variations in prices are presumed to reflect differences in price for the same commodity. Yet there clearly are differences in quality and differences in what is included in the price of hospital beds. Consequently some of the price differences Rosenthal observed are equalizing differences.

Rosenthal is silent about the problem of multicollinearity among his independent variables when one suspects that they are highly correlated. All in all, it is difficult to accept Rosenthal's findings without a great deal of qualification.

REUBEN A. KESSEL

University of Chicago

Manpower and Education: Country Studies in Economic Development.

Edited by FREDERICK HARBISON and CHARLES A. MYERS. New York: McGraw-Hill Book Co., 1965. Pp. xiii, 344. \$9.00.

This volume is a valuable addition to the rapidly growing body of literature on the critical role of human resources in economic development. A companion piece and supplement to the editors' *Education, Manpower, and Economic Growth* (New York 1964), it contains a series of case studies on human resource problems and planning in some twelve developing countries, each written by an individual with on-the-scene experience in the country about which he writes, frequently as an adviser to national planners.

In their four-page introduction to the volume, Frederick Harbison and Charles Myers stress the multidimensional nature of human resource development and the consequent necessity for a "strategy" that integrates a broad range of programs. While the country studies collectively cover most of the relevant aspects, there is considerable variation among them in the problems chosen for analysis. For example, Immanuel C. Y. Hsü's interesting essay on higher education in Communist China focuses exclusively on a description and evaluation of trends in the objectives and content of Chinese higher education, with no reference to methods of manpower planning; on the other hand, two-thirds of Rudolph Blitz's paper on Chile presents detailed supply and demand projections for nine specific "high-level" occupational categories, together with a discussion of the methods whereby they were derived.

Despite this diversity in approach and the range of characteristics represented by the countries covered in the volume (Argentina, Peru, Puerto Rico, Iran, Indonesia, Senegal, Guinea, Ivory Coast, Nyasaland, and Uganda, in addition to those already mentioned) many of the manpower and educational problems alluded to in the papers are common to all or most of them. In addi-

tion to the twin problems of shortages of high-level manpower and surpluses of the unskilled that are virtually universal among developing economies, most of the authors refer to such matters as the geographical maldistribution of professional employees (particularly health personnel); the low ratios of sub-professional to professional personnel (e.g. one nurse for every three doctors in Chile); the qualitative deficiencies in all levels of formal education (e.g. emphasis on rote learning); inadequate arrangements for on-the-job training; and the dearth of innovative and entrepreneurial talent.

At the same time, there are important differences among countries that make each to some degree a unique case. For example, in his essay on "Manpower and Education in Puerto Rico," William H. Knowles points out that the success of Puerto Rico's "Operation Bootstrap" is of only limited usefulness as an example to other developing economies because of the special advantages that inhere in Puerto Rico's relationship to the United States. In an appropriate concluding essay in the volume, Guy Hunter shows how a complex of social, economic, and political factors have created quite different kinds of human resource problems in East Africa (Kenya, Uganda, and Tanganyika) and Malaya on the one hand, and in other Southeast Asian countries (Burma, Indonesia, Thailand, and the Philippines) on the other. The former are characterized by high-quality university education, but extreme shortages of native high-level manpower. The latter, on the contrary, have unemployed surpluses of university-trained manpower, and have sacrificed quality to quantity in educational expansion. Quite different human resource "strategies" are called for in the two instances.

The contributions of George B. Baldwin ("Iran's Experience with Manpower Planning") and of William F. Whyte ("High-level Manpower for Peru") were particularly rewarding to the reviewer. Baldwin sets forth explicitly a conceptual framework for manpower and educational planning in the light of which the Iranian experience is evaluated. He points out that manpower planning and educational planning are overlapping fields in the context of general development planning. Although the formation of occupational skills is a common ground of both, each may make significant contributions to development in other ways. "In addition to training activities outside the educational system, manpower (planning) is concerned also with systems of incentives and mechanisms of labor allocation. Education is concerned with values and goals fully as important to nation building as occupational skills" (p. 146). Although Baldwin's paper does not fully explore all of these dimensions of Iranian experience, it has the merit of defining the problem completely and accurately.

Whyte's paper, prepared in cooperation with Graciela Flores, is a broad-gauged economic and sociological analysis of the human resource problem and prospects in Peru. An unusual aspect of the paper is the investigation of the degree to which the occupational preferences of Peruvian youth and the underlying values of Peruvian society are consistent with the requirements of economic development and growth. The findings are somewhat disquieting, and the authors raise the question whether it is possible to "devise a strategy . . . for changing the values of Peruvian culture" and "for changing the social

structure so that individuals with values appropriate to economic growth will more readily rise to leadership positions?" (p. 72). These are not technical "manpower" questions, but their fundamental importance cannot be doubted by any student of economic development.

The editors' deliberate policy of giving the contributors a relatively free hand with respect to the structure and precise content of their essays has made for a publication that should have wide appeal. Considering the volume as a whole, one might have wished for a somewhat longer introduction by the editors that would have elaborated more fully the several aspects of human resource planning—particularly those relating to labor market processes. Secondly, more attention might have been given in some of the papers to the political and social characteristics of the country that have such profound significance for successful planning. Finally, an index would have increased the volume's utility as a reference work. Nevertheless, the book provides a rich source of data on manpower and education, as well as insight into human resource problems in developing economies. Both students and practitioners in the fields of economic development, manpower, and education will find it indispensable.

NOTES

IMPORTANT NOTICE TO MEMBERS

The American Economic Association is again asking members of the economics profession to assist in the collection of data for the National Register of Scientific and Technical Personnel, 1966. We were most happy with the cooperation we received from our members in 1964. The information you provided enabled us to begin a detailed analysis of the economics profession ("The Structure of Economists' Employment and Salaries, 1964", *American Economic Review*, Supplement, December 1965). We hope that you will cooperate with us again this year by completing and returning at your earliest convenience the questionnaire you receive this month.

HAROLD F. WILLIAMSON
Secretary

NEW NDEA PROGRAM FOR INSTITUTES

The Higher Education Act of 1965 has added economics as one of the 12 disciplines now eligible for support for institutes for advanced study and teaching under Title 11 of the National Defense Education Act. The Office of Education, following the recommendation of a committee of economists and educators called to advise it, has invited proposals from colleges and universities for institutes in the teaching of economics for the summer of 1967 or for the academic year 1966-67.

There is considerable flexibility as to the exact type of institute, but it must be aimed at helping to develop the economic understanding and teaching ability for economics of teachers in the secondary or primary schools; institutes for college teachers are not eligible for consideration at this time. If suitable applications are received, the Office of Education will consider supporting a substantial number of such workshops for the period indicated above. The legislation provides full financial support for the workshops, including stipends for the high school or primary school teachers participating.

Complete information on the program, including steps to be taken in submitting proposals, can be obtained by writing to Dr. Donald Bigelow, Officer in Charge, Division of Educational Personnel Training, Bureau of Elementary and Secondary Education, U.S. Department of Education, Washington, D.C.

This new program is in addition to the program of the National Science Foundation, with somewhat similar aims, which has been in operation for the past two years.

Announcements

The AEA and the Institute of International Education announce the ninth session of the Economics Institute, June 30 to August 31, 1966, at the University of Colorado, Boulder, Colorado. The Institute provides a summer training program for selected foreign students who have been admitted to regular graduate study in economics at universities and colleges in the United States.

Application forms and scholarship information can be obtained from the Institute of International Education, 809 United Nations Plaza, New York, N.Y. 10017 or from the Director of The Economics Institute, Professor Wyn F. Owen, University of Colorado, Boulder, Colorado 80304.

The Survey Research Center of the University of Michigan will once again hold a Summer Institute in Survey Research Techniques. The 1966 Institute will be presented in two four-week sessions, the first from June 27 to July 21 and the second from July 25 to August 18. These two sessions may be taken independently or successively. For further information please write to the Survey Research Center, University of Michigan, P.O. Box 1248, Ann Arbor, Michigan 48106.

The Graduate School of Business and Public Administration of Cornell University has announced a program in international development studies designed for persons interested in administrative careers and advisory services abroad. Under the Master's degree program a person may combine basic courses in administration and public affairs with subjects on the political, social, and economic aspects of development offered throughout the University and in the School. The doctoral candidate may also elect administration and development as a field. Students may participate in any of the four area programs and may include language instruction in any of the 25 languages offered at Cornell. For further information about the program and financial assistance, the applicant should write to Professor Douglas E. Ashford, Malott Hall, Cornell University. Several publications on international studies at Cornell and on the international development program of the School are available on request.

The National Institute of Mental Health provides program grants to departments of economics for pre- and postdoctoral training of students with specific mental health research competencies. Training programs include up to four years of predoctoral training, with stipends, dependency allowances, and tuition support for students; up to two years of postdoctoral training; as well as relevant faculty and other training support. Programs should stress general excellence of disciplinary training and should delimit a clear mental health training research program. Programs are initially underwritten for a maximum of seven years, and, shown merit, may be renewed. Additional information may be obtained from Nathaniel H. Siegel, Social Sciences Section, Training and Manpower Resources Branch, National Institute of Mental Health, Bethesda, Maryland.

The Department of Medical Care Organization of the School of Public Health, University of Michigan, announces the availability of fellowships for a program of study leading to the Ph.D. degree in medical care organization. The program is intended to prepare students for careers in teaching, research, and policy formulation in the sociological, economic, and administrative aspects of medical care organization. Students with a bachelor's or an advanced degree in the social sciences or health fields are invited to apply. The program of study is designed to be completed in three years and to provide competence in the following areas: medical care, relevant aspects of sociology and economics, and research methods.

Fellowship stipends begin at \$2400 for the first year with increments for succeeding years. Stipends are supplemented by an additional \$500 for each dependent and full tuition.

For application or further information, write to Benjamin J. Darsky, Chairman, Doctoral Program in Medical Care Organization, School of Public Health, University of Michigan, Ann Arbor, Michigan 48104.

Deaths

Arthur Z. Arnold, professor of economics, New York University, December 1965.

Andrew Jackson Dadisman, professor emeritus of economics, College of Commerce, West Virginia University, November 8, 1965.

James R. Elliott, Jr., Northern Illinois University, De Kalb, December 1, 1965.

John Thom Holdsworth, professor emeritus and dean emeritus, University of Miami, Florida, October 22, 1965.

Murray G. Lee, American Bankers Association, New York, July 3, 1965.

Harold G. Moulton, President Emeritus, The Brookings Institution, Washington, December 14, 1965.

Weldon Powell, Haskins and Sells, New York, October 23, 1965.

David S. Roswell, New Rochelle, New York.

Rudolph L. Treuenfels, Brooklyn, New York, October 22, 1965.

Retirements

Theodore N. Beckman, professor, department of business organization, Ohio State University, June 1965.

Ralph C. Davis, professor, department of business organization, Ohio State University, September 1965.

Visiting Foreign Scholars

Case A. Cannegieter, University of Western Australia: visiting professor, department of economics, University of Texas, spring 1966.

Will Grader, Nederlands Opleidings Instituut voor het Buitenland: visiting professor, department of finance and business environment, School of Business Administration, University of Oregon.

H. P. Hain, University of Melbourne: visiting professor of accounting, University of Alabama, fall 1965.

Donald M. Lamberton, University of New South Wales: visiting associate professor, business administration and economics, Graduate School of Business, University of Pittsburgh, winter 1966.

Shirley W. Lerner, University of Manchester: visiting professor, School of Labor and Industrial Relations, Michigan State University, winter quarter 1966.

B. H. Schatzmann, University of Neuchatel, Switzerland: visiting associate professor of international marketing, University of Alabama, fall 1965.

C. N. Vakil, University of Bombay and Reserve Bank of India: visiting professor of international business, Graduate School of Business, Indiana University, first semester 1965-66.

Promotions

Irving Abramowitz: professor, department of business organization, Ohio State University.

David L. Bickelhaupt: professor, department of business organization, Ohio State University.

Ernest Bloch: professor, department of banking and finance, School of Commerce, New York University.

Julian H. Bradsher: professor, department of economics, Oklahoma State University.

Lawrence A. Danton: associate professor of economics, Municipal University of Omaha.

Joseph S. DeSalvo: assistant professor of economics, Virginia Military Institute.

Ronald S. Foster: associate professor, department of business organization, Ohio State University.

Harry M. Johnson: associate professor of insurance, finance department, University of Connecticut.

Herbert Kiesling: assistant professor, department of economics, Indiana University.

Benjamin Klebaner: professor, department of economics, City College of New York.

Joseph J. Klos: professor, department of economics, Oklahoma State University.

Vincent De P. Mathews: assistant professor, department of economics, Catholic University of America.

Jean Namias: professor of economics, St. John's University.

David M. Nowlan: assistant professor, department of political economy, University of Toronto.

Roy J. Sampson: professor, School of Business Administration, University of Oregon.

Ned Shilling: associate professor of business statistics, Pennsylvania State University.

Rafael A. Sison: principal economic analyst, Baltimore City Department of Planning, Research and Analysis Section.

E. J. Steele: professor, department of economics, Municipal University of Omaha.

Donald L. Thompson: associate professor, School of Business Administration, University of Oregon.

Elliot Zupnick: professor, department of economics, City College of New York.

Administrative Appointments

Lewis C. Bell, University of Mississippi: director, Tax Research Center, and coordinator of research in business and government, Western Kentucky State College.

Henry W. Briefs: chairman, department of economics, Georgetown University.

Richard R. Carroll: assistant professor and chairman, department of economics, King College, Tennessee.

Edwin B. Cox: assistant dean, College of Business Administration, Boston University.

Rollin O. Dunsdon: chairman, department of economics and business administration, University of the Pacific.

Dascomb R. Forbush: chairman, department of economics, Clarkson College of Technology.

Donald F. Forster: executive assistant to the president, University of Toronto.

C. Edward Galbreath: acting dean, College of General Studies, George Washington University.

Abraham L. Gitlow: acting dean, School of Commerce, New York University.

Rudolph W. Hardy: executive director, New England Economic Research Foundation.

Richard B. Harshbarger: head, department of economics and business, Manchester College.

Charles J. Hitch: vice president, business and finance, University of California, Berkeley.

James H. Hund: dean, School of Business Administration, Emory University.

William N. Kinnard, Jr.: director, Center for Real Estate and Urban Economic Studies, University of Connecticut.

Benjamin Klebaner: assistant dean, College of Liberal Arts and Science, City College of New York.

Richard H. Leftwich: professor and head, department of economics, Oklahoma State University.

Robert Lekachman: chairman, department of economics, State University of New York, Stony Brook.

Richard A. Lester: director, Woodrow Wilson School of Public and International Affairs Graduate Program, Princeton University.

Wesley H. Long: acting director, Center for Economic Research, department of economics, Bowdoin College.

Hugh I. Macdonald, University of Toronto: chief economist, Department of Economics and Development of the Government of Ontario.

Ronald R. Olsen: chairman, department of economics, University of Kansas.

Murray E. Polakoff: chairman, department of economics, School of Commerce, New York University.

Kenneth D. Ramsing: assistant dean, division of undergraduate studies in business administration, University of Oregon.

Edward K. Smith, Boston College: Deputy Assistant Secretary for Economic Policy, U.S. Department of Commerce, Washington.

E. J. Steele: chairman, department of economics, Municipal University of Omaha.

Donald L. Thompson: assistant dean, division of graduate studies in business administration, University of Oregon.

Stan West: director, department of research and statistics, New York Stock Exchange.

Jerome H. Zoffer: assistant dean, academic affairs, associate dean for administration, Graduate School of Business, University of Pittsburgh.

Erratum

The appointment of David LeSourd was listed incorrectly in the December 1965 number

of the *Review*. Professor LeSourd was appointed chairman, department of commerce and economics, University of Vermont.

Appointments

John Q. Adams, III: assistant professor, department of economics, University of Maryland.

H. K. Allen, University of Illinois: visiting professor, department of economics, Southern Illinois University, academic year 1965-66.

Peter L. Arcus: research associate, department of economics, Iowa State University.

Fred D. Arditti, Massachusetts Institute of Technology: staff member, economics department, RAND Corporation.

Roland Artle, University of California, Berkeley: August Röhss Professor of Economics, University of Gothenburg, Sweden.

Francis M. Bator: Deputy Special Assistant to the President for National Security Affairs.

Roger D. Blackwell, Northwestern University: assistant professor, department of business organization, Ohio State University.

Karl Brunner, University of California, Los Angeles: Everett D. Reese Professor of Economics and Banking, department of economics, Ohio State University, fall 1966.

Thomas Burke, Boston College: instructor in economics, Georgetown University.

Kenneth T. Cann: resident lecturer, department of economics, Indiana University, Southeastern Campus.

John M. Cassels: professor, department of economics, University of Colorado, fall 1966.

Perry Chang, Northern Illinois University: associate professor of economics, Municipal University of Omaha.

Ewan Clague, U.S. Department of Labor: distinguished visiting professor, School of Labor and Industrial Relations, Michigan State University, spring quarter 1966.

Darwin B. Close, University of Pennsylvania: assistant professor, department of business organization, Ohio State University.

David W. Cole, Indiana University: assistant professor, department of business organization, Ohio State University.

Donald R. Connell, Iowa State University: assistant professor of economics, Municipal University of Omaha.

Raymond Coward, Louisiana State University: lecturer in business law, University of Alabama.

Edwin B. Cox: professor of statistics, College of Business Administration, Boston University.

Nelson H. Cruikshank, Social Security Department, AFL-CIO: visiting professor, School of Labor and Industrial Relations, Michigan State University, spring quarter 1966.

Douglas C. Dacey, Institute for Defense Analysis, Washington: associate professor, department of economics, University of Texas, spring 1966.

Jim E. Davis, Long Beach State College: program economist, U.S. AID Mission, Morocco.

Francis R. Eels: associate research professor of economics, Institute of Business, Economics and Government Research, University of Alaska.

Betty G. Fishman: lecturer in economics and research associate, Regional Research Institute and College of Commerce, West Virginia University.

Roger N. Folsom: instructor, department of economics, U.S. Naval Postgraduate School.

Robert J. Freeman, University of Arkansas: lecturer in accounting, University of Alabama.

Philip Friedly: assistant professor of planning, division of community and regional planning, Faculty of Graduate Studies, University of British Columbia.

Richard C. Gerhan, Federal Reserve Bank of Cleveland: associate professor, department of economics, Baldwin-Wallace College.

Kenneth Gordon, University of Chicago: instructor in economics, Georgetown University.

George R. Green: assistant professor, department of economics, University of Maryland.

Kanji Haitani, Ohio State University: assistant professor of economics, Southern Illinois University.

Harry H. Hall: research associate, department of economics, Iowa State University.

Stanley T. Hardy, Michigan State University: assistant professor, department of business organization, Ohio State University.

George H. Hempel, Washington University: research fellow, National Bureau of Economic Research.

Mona S. Hersh: assistant professor of economics, Texas Woman's University.

Daniel Howland: associate professor, department of business organization, Ohio State University.

Ichirou Inukai: instructor, department of economics, University of Alaska.

Wells H. Keddie: research director and assistant professor of labor studies, department of labor education, Pennsylvania State University.

Stuart E. Kirby: professor of economics, College of Advanced Technology, University of Aston, Birmingham, England.

David T. Kollat, Indiana University: assistant professor, department of business organization, Ohio State University.

Helen C. Kramer: instructor, department of economics, Brooklyn College.

L. Emil Kreider, Ohio State University: instructor in economics, Southern Illinois University.

Joseph S. La Cascia, University of Florida: assistant professor of economics, Municipal University of Omaha.

Neal B. Long: assistant professor, department of economics, Indiana University, South Bend.

Duncan McDougall, Carleton University, Ottawa: professor, department of economics, University of Kansas, fall 1966.

David L. McKee: resident lecturer, Indiana University, Fort Wayne.

Hillis S. McKenzie: associate professor, department of economics, University of Alaska.

Peter F. M. McLoughlin, World Bank (I.B.R.D.): associate professor of economics, department of economics, University of Santa Clara.

Thomas D. Moore, Tennessee Polytechnic Institute: assistant professor of economics, University of Alabama.

C. J. Nicholas: industry economist, U.S. Department of Agriculture, Hyattsville, Maryland.

Robert E. Osborn, Jr., University of Connecticut: College of Business, Western Kentucky University.

William H. Parks, Michigan State University: instructor, School of Business Administration, University of Oregon.

James W. Petersen, University of Vermont: associate head, logistics department, RAND Corporation.

J. Marion Posey, University of Arkansas: assistant professor of accounting, University of Alabama.

Reed M. Powell, University of California, Los Angeles: professor, department of business organization, Ohio State University.

Frederic L. Pryor: assistant professor, department of economics, Swarthmore College.

James P. Quirk, Purdue University: professor, department of economics, University of Kansas, fall 1966.

Wilbur A. Rapp, Northwestern University: assistant professor, department of business organization, Ohio State University.

H. Dieter Renning, Illinois State University: assistant professor of economics, Kenyon College.

Hugh Rose, University of Toronto: department of economics, University of Rochester.

John B. Ross, Federal Reserve Bank of Dallas: research economist, Bank of America National Trust and Savings Association, San Francisco.

Richard W. Ruppert, University of California, Santa Barbara: assistant professor, department of economics, University of Kansas, fall 1966.

Rubin Saposnik, State University of New York, Buffalo: professor, department of economics, University of Kansas, fall 1966.

T. Paul Schultz, Massachusetts Institute of Technology: staff member, economics department, RAND Corporation.

Leslie L. D. Shaffer, University of Arizona: associate professor, management, School of Business Administration, University of Oregon.

Kenneth L. Shellhammer: instructor in economics and research associate, Regional Research Institute and College of Commerce, West Virginia University.

John W. Snow: assistant professor, department of economics, University of Maryland.

Kenneth T. Strand, OECD: associate professor, department of economics and commerce, Simon Fraser University, December 1966.

Harold K. Strom, University of California, Los Angeles: associate professor of transportation, School of Business Administration, University of Oregon.

Paul Swadener, Indiana University: assistant professor of insurance, School of Business Administration, University of Oregon.

Sydney Turoff, State University of New York, Buffalo: assistant professor of finance, University of Connecticut.

Arlon R. Tussing: assistant professor, department of economics, University of Alaska.

Balder von Hohenbalken: visiting associate professor of economics, department of economics, Iowa State University.

Robert J. Wolfson, RAND Corporation: principal scientist, System Development Corporation, Santa Monica.

G. Donald Wood, University of Pennsylvania: instructor in economics, Georgetown University.

Kenneth L. Wyman: assistant professor, department of political economy, University of Toronto.

Leaves for Special Appointments

Clark C. Bloom, Ford Foundation, Beirut: visiting professor, department of economics, Southern Illinois University, fall term 1965-66.

Lon C. Cesal, Iowa State University: Iowa-Peru project on agrarian reform and economic development under contract with AID, 1966-68.

Frank S. Conklin: Iowa State University: National School of Agriculture, Chapingo, Mexico and University of Nuevo Leon, Monterrey, Mexico, November 1965 for three years.

H. A. J. Green, University of Toronto: Simon Visiting Professor, University of Manchester, England, 1965-66.

Arnold C. Harberger, University of Chicago: International Bank for Reconstruction and Development, autumn 1965.

Douglas G. Hartle, University of Toronto: Royal Commission on Canada's Taxation.

James L. Heskett, Ohio State University: visiting associate professor, Harvard Graduate School of Business Administration.

Benjamin Higgins, University of Texas: senior specialist, East-West Center, University of Hawaii, spring and summer 1966.

Randall A. Hoffman: visiting associate professor, Iowa State University and University of Nuevo Leon, Monterrey, Mexico, October 1965 for three years.

Francis Kutish, Iowa State University: U.S. Department of Agriculture, Washington, November 1965-July 1966.

George W. Ladd, Iowa State University: visiting professor, University of California, Davis, spring 1966.

Ta-Chung Liu, Cornell University: visiting professor of economics, Brandeis University, 1966-67.

Stephen E. McGaughey, Iowa State University: Iowa-Peru project on agrarian reform and economic development under contract with AID, 1966-68.

Philip R. Phillips, New York University: University of Lagos, Nigeria, 1965-66.

Lee E. Preston, University of California, Berkeley: visiting professor, Chinese University of Hong Kong, spring 1966.

Geoffrey S. Shepherd, Iowa State University: Iowa-Peru project on agrarian reform and economic development under contract with AID, September 1965 for two years.

Larry Sjaatad, University of Chicago: University of Minnesota project, AID, University of Los Andes, Bogota, Colombia, winter quarter 1966.

Richard H. Slavins, West Virginia University: Deputy Commissioner of Commerce, Department of Commerce, State of West Virginia.

Wesley J. Yordon, University of Colorado: visiting lecturer in economics, Universidad Autonoma de Guadalajara, Mexico, academic year 1965-66.

Resignations

John Browning, Rutgers—The State University.

James F. Gilson, School of Commerce, New York University.

Richard L. Lesh, Ohio State University.

William E. Schlender, Ohio State University.

Barnard Seligman, School of Commerce, New York University.

Atsushi Suzuki, Indiana University.

William L. Velman, Ohio State University.

Miscellaneous

John H. Prime has relinquished deanship and has been named distinguished professor of finance, School of Commerce, New York University to begin after sabbatical leave, 1965-66.

VACANCIES AND APPLICATIONS

The Association is glad to render service to applicants who wish to make known their availability for positions in the field of economics and to administrative officers of colleges and universities and to others who are seeking to fill vacancies.

The officers of the Association take no responsibility for making a selection among the applicants or following up the results. The Secretary's office will merely afford a central point for clearing inquiries; and the *Review* will publish in this section a brief description of vacancies announced and of applications submitted (with necessary editorial changes). Since the Association has no other way of knowing whether or not this section is performing a real service, the Secretary would appreciate receiving notification of appointments made as a result of these announcements. It is optional with those submitting such announcements to publish name and address or to use a key number. Deadlines for the four issues of the *Review* are February 1, May 1, August 1, and November 1.

Communications should be addressed to: The Secretary, American Economic Association, 629 Noyes Street, Evanston, Illinois 60201.

Vacancies

Medical economist: This is a research position to study economic aspects of hospital and related services in relation to the overall medical and general economy of the state. Requires total of 5 years of graduate training and research experience in economics, including at least 2 years of training or experience in medical or hospital economics. Salary is \$10,898 to \$12,110, plus a wide range of progressive fringe benefits. Send résumé to: Robert P. Mayer, Director of Personnel, N.Y.S. Health Department, 84 Holland Avenue, Albany, New York. 12208

Regional economist: Responsibilities include identification of potential regional research programs, formulation of research proposals for potential sponsors, direction of urban and regional research including those doing desk and field research. The Battelle-Columbus Economics Research Department needs a staff member who has the ability to assess assets and liabilities of local area economics—someone who has working knowledge of literature related to economics and regional analysis. We require an M.S. in economics, economic geography, regional science or a related field. In addition, two years of applicable experience in these fields is required. Salary is commensurate with education and experience. Forward résumé to: L. G. Hill, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio. 43201

Manpower economist: The Battelle Memorial Institute currently has a requirement for a Ph.D. in economic theory, labor economics, or regional economics to supervise projects dealing with projected labor force requirements in areas and nations (some international work involved). He will participate as research staff member of regional economic studies with contributions focusing on the demographic characteristics of regional populations including employment and education. He will also participate in projects dealing with the formulation of educational and training programs at local, state, and national levels. The ability to communicate with research team members drawn from the disciplines of sociology, political science, educational administration, and various process technologies is essential. Added responsibilities include formulation of research proposals and study outline implementation of research design and preparation of oral and written reports. We require experience in regional economic studies, analysis of labor force structure, or general economic forecasting. Salary is commensurate with education and experience. Please forward résumé to: L. G. Hill, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio. 43201

Quantitative economics, business economics: Openings exist at junior and senior levels in statistics and/or operations research and in business economics. Write to: Chairman, Department of Business Economics, College of Business Administration, University of Hawaii, Honolulu, Hawaii. 96822

EDWARD HASTINGS CHAMBERLIN

DISTINGUISHED FELLOW

1965

It is not given to many scientists to reach into the minds of all their fellows and to influence the work of a whole generation, but the author of *The Theory of Monopolistic Competition* did so. The nature of products, the character of intercommodity competition, the accommodation of selling costs in price theory, and the theory of oligopoly have all undergone major change because of Chamberlin's great work.

SOME ESTIMATES OF THE COST OF CAPITAL TO THE ELECTRIC UTILITY INDUSTRY, 1954-57

By MERTON H. MILLER AND FRANCO MODIGLIANI*

In its simplest form, the central normative proposition of the micro theory of capital is that the firm should adjust its capital stock until the marginal rate of return on further investment (or disinvestment) is equal to the cost of capital. Under conditions of perfect certainty—which is the assumption on which most of classical theory has been developed—the concept of the cost of capital presents no particular difficulty. It is simply the market rate of interest. Since all securities must have the same yield in equilibrium under certainty there is only one such rate per period, and it is, in principle, a directly observable magnitude. Under real-world conditions, however, we are confronted not with one, but with a bewildering variety of securities, with very different kinds and priorities of claims to portions of the (uncertain) future earnings of the firm. Since these securities will also, in general, have different anticipated yields, it is by no means clear which yield or combination of yields is the relevant cost of capital for rational investment planning. Nor, because it is based on anticipations, is the cost of capital any longer a directly observable magnitude. It must, rather, somehow be inferred from what is observable, namely, the market prices of the various kinds of claims represented by the different securities.

Although most (but not all) recent studies of investment behavior have shown some awareness of these difficulties, a common approach in empirical work has been simply to ignore the problem and to use

* [The authors are, respectively, professor of finance and economics at the Graduate School of Business, University of Chicago and professor of economics and industrial management at Massachusetts Institute of Technology.]

In the course of the several years during which this paper has been in preparation we have been fortunate in having the assistance of many institutions and individuals. In particular, we wish to express our thanks to (1) The Ford Foundation which has subsidized the project in a variety of ways ranging from Ford Faculty Research Fellowships to the authors to research grants to both schools for the project; (2) the Research Committees of the Graduate School of Business of the University of Chicago, Sloan School of Management, Massachusetts Institute of Technology, and the Graduate School of Industrial Administration, Carnegie Institute of Technology for providing us with additional time for research and for bearing much of the (heavy) cost of computer programming and calculation; (3) our student research assistants, including Clark Armstrong, Stephen Furman, Peter Gustafson, Gardner Heydrich, Anthony Johnson, Myron Scholes, Robert Sharp, Theodore Van Wormer, and Robert Williamson; (4) our many colleagues past and present, with whom we have discussed the various problems of substance and methodology in the paper, including William Alberts, Eugene Fama, Zvi Griliches, Arnold Harberger, Dale Jorgenson, Edwin Kuh, Albert Madansky, Henri Theil, H. Martin Weingartner, Arnold Zellner, and especially Jacques Drèze and Lester Telser. To the extent that there are errors remaining, this must be attributed not to their failure to point them out, but only to our failure to listen.

without comment or explicit justification some standard index of current, nominal yields on high-grade corporate bonds (or even government bonds) as a measure of the cost of capital. Other writers use both a current bond yield series to approximate the cost of debt capital and a current profit series to measure the "availability" and hence, presumably, also the "cost" of equity capital. Still others have tried indexes of share prices, current dividend yields, or current earnings yields alone or in various averages with bond yields along lines suggested in the standard texts on corporation finance. How much error is involved in the use of such measures is still unknown, though even a cursory survey of the underlying theory suggests many grounds for apprehension on this score. But we cannot be sure. Too little work has yet been done to permit even a rough calibration of these series as proxies for the cost of capital, let alone to provide acceptable alternative series.

It is the purpose of this paper to take at least some first steps toward closing this gap in our information about the factors affecting investment. We shall attempt here to develop effective methods for inferring the cost of capital relevant for optimal investment decisions from data on the market values of securities. As a concrete application of these techniques—which we hope will prove of interest not only to economists concerned with understanding investment behavior, but also to the many corporate officials we know to be currently engaged in similar investigations—we shall present some actual estimates of the cost of capital for a sample of large electric utilities for the years 1954, 1956, and 1957.

The sample consists of 63 separate firms representing all of the (consolidated) systems classified as of 1950 as Class A by the Federal Power Commission;¹ plus those of the smaller Class B systems whose assets devoted to electricity generation were at least \$15 million in 1950. The cutoff at \$15 million was, of course, an arbitrary one and represented what we hoped would be a workable compromise between our desire to have as large a sample as possible and yet to avoid having to find valuations for many small companies whose securities are not widely held or actively traded. Consolidated systems rather than individual companies were used to avoid the many problems (both of accounting and of valuation) posed by intercompany holdings of securities. A list of the included companies is appended as Appendix A.

As a testing ground for techniques of estimating the cost of capital the large utilities offer a number of important advantages. They permit us to have both a large sample and one in which the component firms are remarkably homogeneous in terms of product, technology, and

¹ Except for the Hartford Electric Light Company whose accounts could not be adequately reconstructed and made continuous over the entire sample period.

market conditions. In addition, as a by-product of regulation, substantially uniform accounting conventions (down to even such small, but often annoying, details as choice of fiscal year) are followed throughout the industry. In the years studied, moreover, earnings have been highly stable with few of the wide swings in year-to-year reported earnings due to strikes, cyclical or competitive shifts in demand, write-offs of assets, mergers, and the like that often render the published earnings figures virtually meaningless in more sprawling and less sheltered sectors.

As for the sample years, we are embarrassed to have to admit that 1957 was chosen because it was the latest full year available when we began this study. The year 1954, we felt, would be far enough back to show up any significant trend in the cost of capital, but not so far back as to create problems of continuity for the companies in the sample. Since there were some months of business recession in both these years we included the boom year 1956 in the sample in the hope that it might provide some evidence on cyclical swings in the cost of capital if such were sizable or important.

The paper itself will be presented in four main sections. We begin in Section I by providing an operational definition of the cost of capital and developing therefrom the link between cost of capital and market valuation (largely along lines set forth in our previous papers [14] [15] and [17]). Section II describes the econometric model and techniques to be used in estimating the cost of capital. The estimates themselves are presented along with some tests of the specification in Section III. Section IV provides an economic interpretation of the results and a comparison, insofar as that is possible, with other, more conventional estimates.

1. Valuation and the Cost of Capital

As used throughout, the term cost of capital, C , will be taken to mean that minimum prospective rate of yield that a proposed investment in real assets must offer to be just **worthwhile** undertaking from the standpoint of the current owners of the firm. Under conditions of perfect capital markets (and even in some special cases where systematic imperfections are present) there is a one-for-one correspondence between "worthwhileness" in the above sense and the current market value of the owners' interest. If the management of the firm takes as its working criterion for investment (and other) decisions "maximize the market value of the shares held by the current owners of the firm," then it can be shown (see, e.g., Hirshleifer [8]) that this policy is also equivalent to maximizing the economic welfare or utility of the owners. Thus, valuation and the cost of capital are intimately related.

1. *The Simple Certainty Model*

The precise relation between them is most easily seen in the context of a simple certainty model in which all real assets are assumed to yield uniform, sure income streams in perpetuity and in which the market rate of interest, r , is given and constant over time. If, in addition, we assume perfect capital markets, rational investor behavior, and no tax differentials on different sources of income, then it can readily be shown that the equilibrium current market value, V , of any firm (i.e., the sum of the market values of all securities or other claims to its future earnings) is given by

$$1) \quad V = \frac{1}{r} X,$$

where X is the (uniform) income per period generated in perpetuity by the assets presently held. The term $1/r$ in (1)—the reciprocal of the interest rate—is commonly referred to as the market “capitalization rate” for sure streams since it represents the factor the market applies to a unit income flow in converting it to a capital stock.

For an expansion of real assets to be worth undertaking from the standpoint of the current owners of such a firm, the investment must lead to an increase in the market value of their holdings. If we let IA = the purchase cost of the assets acquired, dS^o = the change in value of the holdings of the original owners, and dS^n = the market value of the additional securities issued to finance the investment, then differentiating (1) with respect to A yields:

$$2) \quad \frac{dV}{dA} = \frac{dS^o}{dA} + \frac{dS^n}{dA} = \frac{dS^o}{dA} + 1 = \frac{dX}{dA} \frac{1}{r}.$$

It follows that the cost of capital, C , must be the reciprocal of the market capitalization rate for earnings since from (2), $dS^o/dA \geq 0$ if, and only if, $dX/dA \geq r$, i.e., if, and only if, the rate of return on the new investment is equal to or greater than the market rate of interest.²

3. *Extension to the Case of Uncertainty*

When we turn from a world of certainty to one of uncertainty, the problem of defining the cost of capital in operational terms becomes a much more formidable one for which no completely general solution is yet available. We have at least been able to show, however (see [15]),

² We have here stated (and shall continue to state) the conditions for optimality of investment decisions in terms of the rate of return or internal yield on investment. Although it is well known that there may be cases in which such a rate of return cannot be adequately or unambiguously defined (see, e.g., Hirshleifer [8]), such cases are largely ruled out by our additional simplifying assumptions.

that if we retain the assumptions of perpetual streams, rational investor behavior, perfect markets, no taxes (and no "growth" in a sense to be more precisely defined later), then an analog of the certainty valuation formula (1) does carry through to the case of uncertainty. In particular, if we restrict attention to what we have called a "risk equivalent class" of firms, then the equilibrium market valuation of any firm in such a class can be expressed as

$$(3) \quad V = \frac{1}{\rho_k} \bar{X} \quad \text{for all firms in class } k$$

where V is the sum of the market values of all the firm's securities; \bar{X} is the *expected* level of average annual earnings generated by the assets it currently holds; and where $1/\rho_k$ can be interpreted as the market's capitalization rate for the expected value of uncertain, pure equity earnings streams of the type characteristic of class k .³ Hence, by a straightforward extension of the reasoning in the previous section, the cost of capital for a proposed expansion in scale by any firm in the class is simply ρ_k .⁴ The precise value of ρ_k will, of course, be different from

³ At the level of pure theory a "risk-equivalent class" can be defined in precise terms as a collection of firms such that the elements of the (uncertain) future earnings stream of each firm is proportional to (and hence perfectly correlated with) those of every other member of the class. (See [15].) For empirical purposes, however, the best that can usually be done is to work with reasonably homogeneous industries and hope that the differences among firms are small, random and not strongly correlated with any of the explanatory variables. As noted above, the utility industry probably has the best prospects for meeting these tests and that is one of the reasons why we chose it. It is perhaps also worth noting in this connection that a recent study of comovements among security prices by King [10a] does find strong (but, of course, far from perfect) correlation of price movements within most of the two-digit industries studied including the electric utility industry.

⁴ The fact that under uncertainty we have to allow, in principle, for financing by many different types of securities creates no very serious difficulty. To illustrate, let dS^u = the value of any new shares floated and dD = the value of any additional debt floated. Then from (3)

$$\frac{dV}{dA} = \frac{dS^u}{dA} + \frac{dS^d}{dA} + \frac{dD}{dA} = \frac{d\bar{X}}{dA} \frac{1}{\rho_k},$$

and it is easily seen that

$$\frac{dS^u}{dA} \geq 0 \quad \text{requires} \quad \frac{d\bar{X}}{dA} \geq \rho_k$$

regardless of whether the new investment is financed entirely by stock

$$\left(\frac{dS^u}{dA} = 1 \quad \text{and} \quad \frac{dD}{dA} = 0 \right)$$

or by bonds

$$\left(\frac{dD}{dA} = 1 \quad \text{and} \quad \frac{dS^u}{dA} = 0 \right)$$

or by any combination of the two. Note that for simplicity we here and throughout ignore the possible second-order repercussions of the financing method used on the market value of any already outstanding debt.

class to class, presumably increasing with the market's uncertainty as to the level of future long-run earnings in the class (and reflecting also the nature and extent of the covariation with the returns in other classes). Though the various ρ 's themselves would not be directly observable they could, in principle, be inferred from the market valuations, e.g., by regressing the observed V on estimates of \bar{X} over a cross section of firms within a class.⁵

An important implication of (3) is that the market value of a firm depends only on its real earning power and on the market capitalization rate for pure equity streams of its class, and not at all upon the particular mix of security types that characterize its financial structure. This independence of value and financial structure is basically a reflection of the assumption of perfect capital markets—an assumption implying, among other things, that for comparable collateral, the supply curve of borrowed funds for individuals is the same as that for corporations. Hence if corporations making heavy use of borrowed funds should sell, say, at a premium relative to unlevered corporations in the same class, rational investors could always obtain a more efficient portfolio by selling the “overvalued” levered shares, purchasing the “undervalued” unlevered shares, and restoring the previous degree of leverage by borrowing against the shares on personal account. And conversely if levered shares should sell at a discount, in which case the “arbitrage” operation involves selling the unlevered shares, buying the levered shares, and unlevering them by also buying a pro rata share of the firm's debts.⁶

With reference to the cost of capital, the independence of market value and financial policy implies, of course, that the cost of capital relevant for investment decisions is also independent of how the investment is to be financed, even though the particular securities considered may, and in general will, have very different expected yields. This seeming paradox disappears as soon as it is recognized that the

⁵ Although ρ_k is a constant over the class, it need not, of course, be regarded as a constant over time. Variations in ρ_k over time will create no serious additional problems with the interpretation of (3) as a perpetuity formula so long as such changes in ρ_k as occur are in the nature of “unanticipated” changes (as would be the case, for example, if the process governing the behavior of $\Delta\rho_k$ over time were essentially a random walk with zero mean). Note also that the assumption that all assets generate perpetual streams is less restrictive than might appear at first sight. The perpetuity valuation formulas may still be good approximations at the level of the firm as a whole even where the component assets have finite lives, provided that the firm is close to a steady state in which replacements balance depreciation and provided \bar{X} is interpreted as net earnings after depreciation (but before interest).

⁶ A fuller account of the arbitrage mechanism and proof of the independence proposition is given in our [15]. It is perhaps worth noting that the independence proposition can be proved under assumptions much weaker than those necessary to develop equation (3). In particular, neither the perpetuity assumption nor the concept of a risk equivalent class is essential (see, e.g., the discussion in our [14, pp. 429–30] and also Hirshleifer [9]).

independence property also requires that the common shares in levered corporations have higher expected yields than those of less levered corporations in the same class—a differential which can be thought of as compensation for the greater “riskiness” attaching to levered shares. Thus, the apparent gain in terms of the cost of capital coming from the ability of a firm to finance an investment with “cheap” debt capital is offset (and with rational behavior in a perfect capital market exactly offset) by the correspondingly higher cost of equity capital.⁷

The reason for this effect can perhaps be seen somewhat more readily by deriving from (3) an explicit expression for the value of the shares in terms of net profits and financial structure. Making use of the identities $V \equiv S + D + P$ (where S = the market value of the common stock, D = the market value of the firm's debts, and P = the market value of the preferred stock) and $\bar{X} \equiv \bar{\pi} + \bar{R} + \bar{P}dv$ (where $\bar{\pi}$ = expected net profits to the common shareholders, \bar{R} = expected interest payments and $\bar{P}dv$ = expected preferred dividends) it is easily seen that (3) implies

$$(4) \quad S = \frac{1}{\rho_k} \bar{\pi} - \left(D - \frac{\bar{R}}{\rho_k} \right) - \left(P - \frac{\bar{P}dv}{\rho_k} \right).$$

The market value of the debt, D , represents the capitalized value of the expected interest stream \bar{R} ; and since the interest component of total expected earnings is less “risky” than the stream of earnings itself (at least over the range of leverage that safety-oriented creditors normally permit), it will tend to be capitalized more favorably than the rate $1/\rho_k$. Hence $(D - (\bar{R}/\rho_k))$ and $(P - (\bar{P}dv/\rho_k))$ are positive and may be thought of as in the nature of risk discounts to be subtracted from capitalized net profits in arriving at the value of the shares.

Note finally that (4) could serve equally well, in principle, with (3) as a cross-sectional valuation equation from which to infer $1/\rho_k$. Clearly, however, (3) is more efficient (since it requires estimating only a single coefficient) and accordingly will be used here as the basis for estimation.

C. *The Effect of Corporate Income Taxes*

When we extend the analysis to allow for the existence of corporate income taxes and the deductibility of interest payments, the most im-

⁷ References here and elsewhere in the paper to differences in “risk” in relation to differences in expected yields as among securities are, of course, entirely heuristic and intended solely to provide a rationalization of the theoretical results in a way that accords with ordinary, common sense notions about relative valuations. The results themselves, however, are in no way dependent on any special assumptions with respect to risk or “risk aversion”; and readers who find our rationalization in terms of these categories unsatisfactory are free to substitute their own.

portant change is that market value and financial structure are no longer completely independent. To see what is involved let us again denote by $1/\rho_k$ the capitalization rate in a given class for pure equity streams available to investors (i.e., streams of expected net profits after taxes in unlevered firms); by \bar{X} , a firm's expected total earnings, now to be taken as earnings before taxes as well as interest; and let τ be the (constant) marginal and average rate of corporate income taxation. Then the market value of an unlevered firm can be expressed as:

$$(5) \quad V_u = S_u = \frac{\bar{X}(1 - \tau)}{\rho_k},$$

where $\bar{X}(1 - \tau)$ is the unlevered firm's earnings after taxes. The value of a levered firm with D of debt or other securities whose payments are tax deductible can be shown to be:

$$(6) \quad V \equiv S + D + P = \frac{\bar{X}(1 - \tau)}{\rho_k} + \tau D.$$

Note that in (6), the expression $\bar{X}(1 - \tau)$ no longer represents the firm's earnings after taxes or any other standard accounting concept when D is not zero and hence when \bar{X} includes some tax-deductible interest. To avoid confusion, therefore, we shall hereafter refer to $\bar{X}(1 - \tau)$ as "tax adjusted" earnings, using the symbol \bar{X}^T for earnings after taxes in the ordinary accounting sense (i.e., for the sum of expected net profits after taxes, preferred dividends and interest payments as they actually come onto the market for sale to the various security purchasers).⁸

As to the meaning of (6), it says, in effect, that the government pays a subsidy to firms using certain sources of capital which under current law would include bonds, notes, and other firm contractual obligations of indebtedness but not preferred stocks or common stocks.⁹ The addition to the present worth of the firm occasioned by these tax savings is the corporate tax rate times the market value of the debt—the latter

⁸ The relation between the various concepts can easily be established by observing that taxes paid will be $\tau(\bar{X} - \bar{R})$ so that $\bar{X}^T = \bar{X} - \tau(\bar{X} - \bar{R})$ and hence $\bar{X}(1 - \tau) = \bar{X}^T - \tau\bar{R}$. In earlier versions of this paper, we made extensive use of valuation formulas based on \bar{X}^T rather than $\bar{X}(1 - \tau)$ largely because of what we felt was the greater intuitive appeal and familiarity of the former concept. This advantage, however, we now believe is not sufficient to outweigh the loss in the efficiency of estimation relative to the somewhat simpler valuation relations based on the tax-adjusted concept. Furthermore, the concept of tax-adjusted earnings, though not known by that name, is actually a fairly standard concept in the literature on capital budgeting. (See, e.g., [2].)

⁹ There is one exception to the rule that dividends on preferred stocks are not tax-deductible, and that, unfortunately, occurs in the electric utility industry. The deduction, however, is only a partial one and applies only to a limited set of issues (those outstanding as of 1942 or issued subsequently in redemption of such issues). Hence, the error involved in ignoring this complication (as we shall) is not likely to be important for present purposes.

being, of course, the present worth, as judged by the market, of the future stream of tax-deductible payments.¹⁰

With respect to the value of the common shares, the effect of the tax subsidy for interest is to change (4) to

$$(7) \quad S = \frac{1}{\rho_k} \bar{\pi}^r - (1 - \tau) \left(D - \frac{\bar{R}}{\rho_k} \right) - \left(P - \frac{\bar{P}dv}{\rho_k} \right),$$

which can be derived from (6) by noting that $\bar{\pi}^r = (1 - \tau)(\bar{X} - \bar{R}) - \bar{P}dv$ = net profits to the common stockholders after taxes. That the subtraction from S due to debt financing is now reduced to the fraction $(1 - \tau)$ of its former size reflects the fact that the government's claim on the firm's earnings is essentially similar to that of a stockholder (see n. 10). Hence while the government can claim τ per cent of the profits, it must also bear τ per cent of the "risk," including the risk introduced by leverage. In the case of nondeductible preferred stock, no such profit-sharing takes place so that the subtraction due to this form of leverage retains its previous value.

Since the deductibility of interest payments thus makes the value of the firm a function of its financial policy, it must also make the required yield or cost of capital a function of financial policy. To see the precise nature of this dependence, let dS^o , as before, stand for the change in the market value of the shares held by the current owners of the firm; dS^n = the value of any new common shares issued; dP = the value of any new preferred stock issued; and dD = the value of any new tax-deductible debt issued, with $dS^n + dP + dD = dA$. Then from (6) we have:

$$(8) \quad \frac{dV}{dA} = \frac{dS^o}{dA} + \frac{dS^n}{dA} + \frac{dP}{dA} + \frac{dD}{dA} = \frac{dS^o}{dA} + 1 = \frac{d\bar{X}(1 - \tau)}{dA} \frac{1}{\rho_k} + \tau \frac{dD}{dA}$$

¹⁰ Since the proof is developed in detail in [7], we shall not reproduce it here. The reader may, however, easily convince himself of the correctness of (6) by means of the following parable. Suppose that we were back in the no-tax world of formulas (3) and (4) and that all stocks were owned by two families—the G or Government family owning precisely τ per cent of the shares in every corporation and the P or Private family owning the remaining $(1 - \tau)$ per cent plus all the bonds. (For simplicity, ignore preferred stock.) Then the value of the combined stockholdings of both families in a levered firm is:

$$S_L^P + S_L^G = S_L = V_L - D_L^P = \frac{\bar{X}}{\rho_k} - D_L^P.$$

The value of the purely Private family holdings of stocks and bonds in the firm must then be:

$$V_L^P = S_L^P + D_L^P = (1 - \tau)S_L + D_L^P = \frac{\bar{X}(1 - \tau)}{\rho_k} - (1 - \tau)D_L^P + D_L^P = \frac{\bar{X}(1 - \tau)}{\rho_k} + \tau D_L^P.$$

For some additional discussion of this way of looking at the derivation see [18].

from which it follows that the cost of capital or required yield on a tax-adjusted basis is

$$(9) \quad C = \rho_k \left(1 - \tau \frac{dD}{dA} \right)$$

since $dS^0/dA \geq 0$ if, and only if, $d\bar{X}(1-\tau)/dA$ is equal to or greater than the right-hand side of (9).¹¹

In connection with (9) the two extreme cases of financing methods are of particular interest. For an investment financed entirely by equity capital—and remember that in this context equity capital includes non-deductible preferred stock— dD/dA will equal zero. Hence the required tax-adjusted yield or “marginal cost of equity capital” is ρ_k . For an investment financed entirely by debt or other sources of capital whose payments are tax-deductible, dD/dA is unity, implying that the “marginal cost of debt capital” is $\rho_k(1-\tau)$.

The term “marginal cost” has been placed in quotes to emphasize that while these extreme cases serve to illuminate the meaning of (9), neither is directly relevant for actual decision-making at the level of the firm. In companies large enough to have ready access to the capital markets, as would certainly be true of those in our sample, investment and financing decisions (including decisions to retire outstanding securities) are made continuously and largely independently over time. Since particular investment projects thus are not, and in general cannot, be linked to particular sources of financing, the relevant cost of capital to the firm must be thought of as essentially an average of the above costs of debt and equity capital with weights determined by the long-run average proportions of each in the firm’s program of future financing. If we denote this “target” proportion of debt as L , then the weighted average cost of capital can be expressed as $C = C(L) = \rho(1-\tau)L + (1-L)\rho$, or, more compactly as $C = C(L) = \rho_k(1-\tau L)$, where the notation $C(L)$ will be used when we want to emphasize that the cost of capital is a *function* of the target debt ratio L .¹²

¹¹ Alternatively, the required yield could be stated in terms of *before-tax* earnings, \bar{X} as $\rho_k(1-\tau(dD/dA))/(1-\tau)$. There would, of course, be no reason to prefer one concept of earnings over the other as long as the perpetuity interpretation of the earnings stream is strictly maintained. The tax-adjusted yield, however, can be shown to be the relevant one for decision-making when the analysis is extended to admit assets with finite lives and, accordingly, will be used here throughout. (Cf. notes 5 and 8 above and also the discussion in our [17, n. 16].)

¹² The determination of the optimal value of L for the firm involves many difficult issues for which no completely well-worked-out theoretical analysis is yet available. Suffice it to say here only that it does not follow that because debt is subsidized we must expect to find all firms in any class with the same degree of leverage and that at the maximum permitted by lenders. The subsidy to debt is at least partially offset by other costs incurred (and not adequately comprehended in simple static models of valuation of the kind here considered) as well as by possible interactions between debt and earnings. The utility industry provides a

Notice, finally, that while the definition of the cost of capital has become a good deal more complex as a result of the introduction of corporate income taxes, the problem of estimation remains essentially the same. It still involves only the estimation of a single capitalization rate—in this case $1/\rho_k$, the capitalization rate for unlevered, pure equity streams in the class. The difference between the cost of equity and debt capital introduces no new difficulties because the cost of debt capital does not depend on the market rate of interest on bonds, but only on the above capitalization rate and the tax rate. Hence $1/\rho_k$ remains a sufficient parameter both for economists seeking to explain rational investment behavior and for firms planning their investment programs on the basis of given financial policies.¹³

D. *Growth and Valuation*¹⁴

Up to this point, we have been focusing attention entirely on the role of current earning power and financial policy as determinants of the value of the firm. There are, of course, very many other factors that influence real-world valuations and some that may well be large enough and systematic enough to warrant incorporating them directly into the model rather than impounding them in the general disturbance term. Of these, one of the most important is "growth potential," in the sense of opportunities the firm may have to invest in real assets in the future at rates of return greater than a "normal" rate of return (i.e., greater than the cost of capital)

Clearly, translating such a concept into operational terms is a task of formidable proportions and one for which no universally applicable solution can be expected. For industries such as the electric utilities,

particularly good example of the latter since corporate income taxes are deductible in computing earnings allowed on the rate base. To the extent that tax is thus passed on, the ultimate value of the tax subsidy on interest is correspondingly reduced (i.e., the total derivative of debt on value will be less than the partial of D on V given \bar{X}). Nor, finally, do firms always have a completely unrestricted choice as to their future debt policies, either because of restrictions incorporated in already outstanding debts or because, as in the case of the utilities, the regulatory authorities may impose upper (and in some cases allegedly even lower) bounds on debt levels.

¹³ The independence of the cost of equity capital (and hence also of debt capital) from the interest rate is, of course, an independence only within a partial equilibrium framework. In a general equilibrium setting, there is necessarily a very direct connection between the interest rate (which may be regarded to a first approximation as the yield on assets generating sure streams) and the various ρ_k (which are the expected yields on assets generating streams of various degrees of uncertainty). But while the connection is direct (since they are mutually determined in the process of market clearing and jointly reflect such underlying factors as the level of wealth, the composition of the stock of real assets, attitudes toward risk and the like), there is no reason to believe that they must move closely together over time.

¹⁴ N.B. Since all of the main earnings and cost of capital concepts have now been introduced we shall hereafter, in the interests of simplicity, drop all subscripts and superscripts on the variables where there is no danger of ambiguity.

however—where the growth in earnings has been (and will presumably continue to be) reasonably steady—rough, but tolerable, approximations to growth potential can probably be obtained by exploiting the so-called constant-growth model. In particular, suppose that a firm has the opportunity to invest annually an amount equal to $100k$ per cent of its tax-adjusted earnings ($k \leq 1$), on which investments it will earn a tax-adjusted rate of return of ρ^* , greater than $C = C(L)$, its average cost of capital. (These assumptions imply, among other things, that earnings will grow at the constant rate of $k\rho^*$ per year.) And suppose further that these especially profitable opportunities are expected to persist over the next T years, after which only normally profitable opportunities will be available. Then, by analogy to the solution we have derived for the certainty case (see [14, n. 15]), the current market value of the firm can be expressed as

$$(10) \quad V = \frac{1}{\rho} \bar{X}(1 - \tau) + \tau D + k\bar{X}(1 - \tau) \left[\frac{\rho^* - C}{C(1 + C)} \right] T,$$

where the first two terms, as before, represent the capitalized value of the current tax-adjusted earning power plus the tax benefits on debt; and the last term is the contribution to value of the future growth potential.^{15,16}

Despite the heroic simplifications invoked in its derivation, the above expression for growth potential is still by no means a simple one. It is the *product* of three separate elements: the profitability of the future opportunities as measured by the difference between ρ^* and $C(L)$; the size of these opportunities $k\bar{X}(1 - \tau)$; and how long they are expected to last T . None of these component terms is directly observable, though some such as $k\bar{X}(1 - \tau)$ and possibly ρ^* might be approximated by extra-

¹⁵ Several considerations led to our use of the above finite growth model rather than the more popular infinite growth model (see Gordon [7] or Lintner [12]) which (taxes and leverage aside) leads to the familiar valuation formula

$$V = \frac{X(1 - k)}{\rho - k\rho^*}.$$

The finite model does capture at least the essence of the S-shaped growth path which is encountered so frequently (and for good economic reasons) in empirical studies of firm and industry development. The infinite model, moreover, requires that k be strictly less than unity and $k\rho^*$ strictly less than ρ for a stable equilibrium value of the firm to exist at all; and, as a practical matter, for k and $k\rho^*$ to be substantially below these limits to avoid absurdly high valuations. In our sample, however, k is in the neighborhood of two in all three years and, we might add, that this is by no means an exceptional case. The value of k has been quite close to unity for the corporate sector as a whole in recent years.

¹⁶ The expression for growth potential in (10) differs from that in [14, n. 15] by the inclusion of the term $(1 + C)$ in the denominator. The new expression given here is the correct one, and we are grateful to H. M. Weingartner for calling our attention to the slip in the original derivation.

polating recent past experience. Accordingly, we shall, in this paper, take the simplest way out by focusing on the most tractable component $k\bar{X}(1-\tau)$, the level of investment opportunities, and impounding the others in its regression coefficient.¹⁷

As an empirical estimate of investment opportunities, we have used in the subsequent estimating equations the quantity $(1/5)(A_t - A_{t-5})/A_{t-5} \cdot A_t$. That is, we have used a linear 5-year average growth rate of total assets times current assets. This particular form of average, denoted for simplicity hereafter as $\bar{\Delta A}$, happens to yield consistently higher gross and net correlations with total value than other simple smoothings we have tried. But the differences are not large and the estimates of the other coefficients are not sensitive to the specific measure used.

E. Dividend Policy, Valuation, and the Cost of Capital

Under ideal conditions of perfect capital markets, rational investor behavior, and no tax discrimination as between sources of income, dividend policy would present no particular problem. In such a setting, we have shown [14] that, given a firm's investment policy, its dividend policy will have no effect whatever on the current market value of its shares or on its cost of capital; and that despite the impressions of some writers to the contrary (see, e.g., Lintner [11]), this conclusion is equally valid whether one is considering a world of certainty or uncertainty. Dividend policy serves to determine only the division of the stockholders' return as between current cash receipts and capital appreciation; and the division of the firm's equity financing as between retained earnings and external flotations.

The picture becomes considerably more complicated, however, as soon as we weaken the assumptions to allow for the present tax subsidy on capital gains and for the existence of substantial brokerage fees and

¹⁷ Needless to say, the particular approach adopted here with respect to representing the growth variable is not to be regarded as of general applicability and was chosen, at least in part, with a number of very special properties of the electric utility industry in mind. First, growth in earnings and assets in the utility industry does tend to be fairly steady from year to year and there is, in particular, no problem of large spurts in growth due to mergers or acquisitions. Hence current and recent past investment levels do provide at least a meaningful starting point for estimates of future investment. Second, because of the regulated status of the industry there is reason to believe that what has been impounded in the coefficient, namely,

$$\left(\left[\frac{\rho^* - C}{C(1 + C)} \right] T \right),$$

is not only of the same sign, but at least roughly of the same order of magnitude for all companies. Certainly we do not have the wide dispersion in rates of return that would characterize, say, the railroad industry (where it is not unreasonable to suppose that for some lines ρ^* may even be less than $C(L)$) or the typical manufacturing industry whose component firms are much more exposed to competition from new products and new firms.

flotation costs. Under these conditions, a firm's dividend policy can, in general, be expected to have an effect on its market value, though the precise amount of the effect is impossible to determine a priori. Unlike the case of corporate debt, the tax subsidy to capital gains is not a constant but varies widely from investor to investor (with the subsidy actually being zero for the substantial part of the market represented by pension funds, foundations, etc., and possibly even negative for very small investors by virtue of the dividends-received credit and for corporate investors [including casualty insurance companies] by virtue of the partial exclusion of intercorporate dividends). Moreover, the tax disadvantages of high payout shares may be partly or wholly offset by other influences. Elderly or retired investors—a nontrivial segment of the market—who are decumulating (or at least not further accumulating) their wealth in the form of shares may find considerable savings in brokerage fees and other costs of portfolio adjustment in high payout as opposed to high capital gain securities. Even net accumulators may be induced to hold high payout shares despite their lower after-tax yields either for reasons of control (broadly understood to include shares held by management as an incident to employment) or for reasons of diversification.

Given this uncertainty as to the size, and to some extent even the direction of the dividend effect, the indicated course might seem to be simply to add a dividend term with unspecified coefficient to the structural equation (10) and let the sample determine its value. From such a valuation equation we could, of course, also go on to derive an extension of the cost of capital formula (9) running in terms of dividend policy as well as debt policy.¹⁸

The trouble with such an approach, however, is that if applied in straightforward fashion (as in Gordon [6] [7] or Durand [5]), the resulting estimate of the dividend coefficient will inevitably be strongly upward biased (and the key earnings coefficient correspondingly downward biased). Since the precise mechanism generating this bias will be discussed at length in a later section, we need not dwell on the matter further at this point beyond observing that the difficulty arises from the widespread practice of dividend stabilization. With current dividends based in large part on management's expectations of long-run future earnings, the dividend coefficient in the regression equation will

¹⁸ Although the procedure for deriving the marginal and average costs of capital in the dividend case is analogous to that for the leverage case, the derivation is considerably more complicated. Further difficulties arise from the fact that in the presence of such major market imperfections, maximizing market value is no longer always equivalent to maximizing the economic welfare of the owners. Since these and related problems are largely peripheral to the main concerns here, further discussion of them will be deferred to separate papers.

reflect this substantial informational content about $\bar{X}(1-\tau)$ along with the true effect, if any, of dividends per se on valuation.¹⁹

Because of this confounding of the earnings and dividend coefficients, our approach here will be initially to omit the dividend variable entirely, and to focus on the problem of estimating the earnings coefficient (which is, of course, to be interpreted as the capitalization rate for earnings for companies following the sample average dividend policy). As we shall see, the procedures to be developed for obtaining consistent estimates of the key earnings coefficient will also permit us to go on to obtain at least order of magnitude estimates of the true dividend effect for the sample years.²⁰

F. Size and Valuation

All the valuation equations so far considered have been written as linear homogeneous functions of the independent variables, implying among other things that a given proportionate change in the values of all the independent variables leads to an equal proportionate change in the market value of the firm. The results of previous valuation studies (see, e.g., Gordon [7]) suggest, however, that the true market capitalization rate for the expected earnings of large firms may possibly differ systematically from that of small firms in the same industry.

As was true of the growth effect, there are a number of possible ways of incorporating this size or scale effect into the model. By far the simplest—and hence the approach we shall here adopt—is merely to add a constant term to the valuation equation.²¹ The resulting nonhomo-

¹⁹ Another possible source of bias arises from the accelerated depreciation provisions of the Revenue Act of 1954. As a result of the increased deductions permitted, part or all of the dividends paid by some companies in our sample (and in other industries as well) are considered for tax purposes as exceeding accumulated earned surplus and hence as being paid out of "capital." Such returns of capital are not taxable to investors—the investor merely being required to reduce the basis (i.e., "cost") of the security for purposes of computing the capital gain or loss on sale. Since the higher the payout, the higher the probability that the dividend may qualify as tax-exempt, the net effect is likely to be an upward bias in the dividend coefficient.

²⁰ We hasten to add that omitting dividends is, again, not a procedure we would care to recommend for general application; and that like our solution for the growth problem, the approach was adopted, in part, with some of the special properties of the utility industry very definitely in mind. For one thing, payout ratios are far less variable from company to company in this industry so that our eventual estimate of the average capitalization rate for earnings will be a much more representative average than it would be for the general run of industry groupings. Moreover, the average payout ratio is quite high, so much so that utility stocks have long represented the example *par excellence* of "income stocks." Since the clientele attracted to such stocks is likely to be much less sensitive to the tax subsidy to capital gains, the size of the dividend effect (and hence of the specification error involved in omitting it) is also likely to be much smaller here than elsewhere.

²¹ Our reasons for not wanting to introduce a continuous size variable, such as total assets, at this stage will become clear from the discussion of the errors of measurement problem in Section II, below.

geneous equation must then be interpreted as the linear approximation over the sample range to the underlying nonlinear relation, and the coefficient of the earnings variable as the (constant) marginal capitalization rate in the industry. The magnitude and direction of the scale effect would be indicated by the size and sign of the constant term. A negative constant term would mean that the average capitalization rate is less than the marginal and hence that the average capitalization rate tends to rise with increasing size of firm. A positive value for the constant term, on the other hand, would imply decreasing returns to scale in valuation.

G. Summary

Our analysis of the theory of valuation leads to the following structural equation:

$$(11) \quad (V - \tau D) = a_0 + a_1 \bar{X}(1 - \tau) + a_2 \bar{\Delta A} + U,$$

where a_1 is the marginal capitalization rate for pure equity streams in the class, and hence the key parameter for deriving the cost of capital; a_0 is an intercept term whose size and sign will measure any effects of scale on valuation; a_2 is a measure of the effects of growth potential on value; and U is a random-disturbance term. Notice that since the theory implies that the coefficient of the leverage variable D is equal to the marginal corporate tax rate τ , we have so constrained it in the above equation by incorporating it with the dependent variable. There remains the problem of specifying the nature and properties of the disturbance term and it is to this task that we now turn.

II. The Statistical Model

Least-squares estimates of the coefficients of (11) will be efficient and unbiased only if among other things (i) the variance of the disturbance term is a constant, independent of the size of the firm; and (ii) the disturbances are not correlated with the independent variables. Unfortunately, neither of these conditions can reasonably be expected to hold in our sample.

A. Heteroscedasticity

As for the variance of the disturbances, one would certainly suppose that the errors in a valuation equation (including errors in measuring $(V - \tau D)$) are of the multiplicative, rather than the additive variety. And indeed, check of the simple scatter of value on measured earnings suggests that the standard deviation of the error term is approximately proportional to the size of firm. Any attempt to fit (11) directly, therefore, would be highly inefficient and in our sample (where the largest

firm is on the order of 100 times the smallest) the results would be completely dominated by a handful of giant companies.

In the present context, there are at least two approaches worth considering as possible solutions for this problem of heteroscedasticity: (i) dividing (11) through by $(V - \tau D)$ and re-expressing the structural relation in so-called "yield" form; or (ii) weighting each observation in inverse proportion to the size of the firm and hence to the size of the standard deviation of the error.²² The former (which was the approach we adopted in our first paper [15] and which was subsequently followed by Barges [1]), leads to the estimating equation:

$$(12) \quad \frac{\bar{X}(1 - \tau)}{V - \tau D} = a'_1 + a'_0 \frac{1}{V - \tau D} + a'_2 \frac{\overline{\Delta A}}{V - \tau D} + u',$$

where $a'_1 = \rho$ = the reciprocal of the capitalization rate for pure equity streams (or, equivalently, the "marginal cost of equity capital");

$$a'_0 = -a_0\rho; a'_2 = -a_2\rho; \text{ and } u' = -\rho \frac{U}{V - \tau D},$$

with $\text{Var}(u')$ approximately a constant for all firms.²³

While an approach of this kind has the virtue of simplicity, it suffers from the fact that the variable $(V - \tau D)$ enters into the denominator of the ratios on both sides of the equation. This is not only somewhat unesthetic—since we are, in effect, using V to explain V —but will lead to biased estimates to the extent that $(V - \tau D)$ contains stochastic

²² A third possibility, of course, would be to use the logarithms rather than the natural values of the variables, but this would be inappropriate since the growth term, as we have here derived it, enters as an additive rather than a multiplicative or exponential term. It could be argued, of course, that given the heroic assumptions underlying that growth variable, the additional specification error introduced by the log transform is not likely to be of overwhelming concern and there is certainly some merit in this position. The trouble is, however, that our interest here is both in estimating the cost of capital and in testing certain hypotheses about valuation. For the latter purpose, as we shall see, additional variables must be incorporated into the equations and these very definitely enter in linear form. Since the other methods for dealing with heteroscedasticity are entirely adequate for that purpose and also carry through more naturally to the testing problem, we shall work with them exclusively in the sections to follow.

²³ An alternative form of yield equation, though somewhat less convenient, would be

$$(13) \quad \frac{\bar{X}(1 - \tau)}{V} = a''_1 \left(1 - \tau \frac{D}{V}\right) + a''_0 \frac{1}{V} + a''_2 \frac{\overline{\Delta A}}{V} + u'',$$

where $\bar{X}(1 - \tau)/V$ can be interpreted as the tax-adjusted earnings yield on total value (approximately the "average cost of capital" of the finance literature) and $a''_1 = \rho$. Note that considerations of efficiency suggest using the quantity $(1 - \tau D/V)$ as the leverage variable and suppressing the constant term rather than estimating separately a constant term and a coefficient for D/V as is usually done when (13) or variants of it are fitted to the data.

The economic meaning of yields such as $\bar{X}(1 - \tau)/V$ and $\bar{X}(1 - \tau)/(V - \tau D)$ and their relations to the cost of capital will be considered at length in Section IV, below.

elements independent of those in the numerator of the ratios. In the present case, this will mean that the coefficients of the growth and size variables will be too high (i.e., less negative) and that the estimate of the cost of capital (from the intercept term a'_1) will be correspondingly too low. Since $(V-\tau D)$ certainly does have a stochastic component—impounded in the term U in (11)—and since we have, at this stage, no basis for judging how large the resulting bias really is, we obviously cannot afford to rely exclusively on estimating equations of this form.²⁴ Instead, we shall use them here essentially only for checking the reasonableness of the estimates obtained via the weighted regression approach.

As for implementing the weighted regression approach, the fact that the standard deviation of the error term in (11) is roughly proportional to size of firm means that the required weighting can be effected by the relatively simple expedient of deflating each of the variables by some scale variable such as the book value of total assets, denoted by A . Our reason for using total assets as a deflator rather than, say, total sales (as, e.g., in Neilsen [19]) is mainly that in the utility industry at least such deflated terms as V/A , D/A , or $\bar{X}(1-\tau)/A$ have natural and useful economic interpretations in their own right. The equation to be fitted, then, will be of the form

$$(14) \quad \frac{V - \tau D}{A} = a_0 \frac{1}{A} + a_1 \frac{\bar{X}(1 - \tau)}{A} + a_2 \frac{\bar{\Delta A}}{A} + u,$$

with $u = U/A$ and $\text{Var}(u) = \text{a constant}$.

One question that immediately arises in connection with (14) is the status of the constant term. Recall that we are interpreting the basic valuation equation (11) in the original, undeflated variables as a linear approximation over the sample range, with its constant term a_0 serving as a measure of the effect of scale on valuation. To preserve this interpretation we must, therefore, regard the derived deflated regression (14) as homogeneous, that is, as being fitted with no constant term and with the coefficient of the variable $1/A$ now measuring the size effect. Failure to suppress the constant term in the deflated regression would imply that the book value of total assets appears along with expected future earnings as one of the explanatory variables in the original equation—a specification that makes little sense from the standpoint of the theory of valuation. We shall, of course, attempt to check the validity of the assumption that the regression in deflated form has a zero constant term, but there are complications involved, as will become clear from the discussion in the next section.

²⁴ The problem of bias in the yield-form tests is further considered in note 28, below.

B. *Errors of Measurement in Expected Earnings*

In using an equation such as (14) to estimate the cost of capital, the key variable is, of course, $\bar{X}(1-\tau)/A$, defined, it will be recalled, as the market's expectation of the long-run, future, tax-adjusted earning power of the assets currently held by the firm. Since it is an expectation, it is not directly observable or measurable and the best that can normally be done is somehow to approximate it from the firm's published accounting statements. This best, unfortunately, is likely to be none too good even in an industry such as the electric utility industry where there is substantial uniformity of accounting conventions among firms; where there are, at least in our sample period, no firms suffering net losses; and where large, year-to-year random fluctuations in reported earnings seem to be relatively rare.

The implications of these inevitable errors in the measurement of earnings for the problems at hand are perhaps most easily seen by expressing the underlying structure as the following *system* of equations where, to simplify the notation we let

$$V^* = \frac{V - \tau D}{A}; X^* = \frac{\bar{X}(1 - \tau)}{A} = \text{the "true" unobservable expected earnings};$$

X = deflated earnings as measured from the accounting statements; and $Z_i, i = 1 \dots m$, stand for all other relevant variables (including constants, where appropriate):

$$\begin{aligned} (1) \quad V^* &= \alpha X^* + \sum_{i=1}^m \beta_i Z_i + u \\ (15) \quad (2) \quad X &= X^* + v \\ (3) \quad X^* &= \sum_{i=1}^m \gamma_i Z_i + w, \end{aligned}$$

where some γ_i and β_i may be zero; and with the error terms assumed to be independent of each other and to have mean zero and (constant) variances σ_u^2 , σ_v^2 , and σ_w^2 , respectively. In words, the value of the firm depends on expected earnings and certain additional explanatory variables; measured earnings are merely an approximation to true expected earnings, the error of measurement being v ; and lastly, some, at least, of the explanatory variables are also correlated with (and hence convey information about) the true, but unobservable X^* .²⁵

²⁵ Note that we have assumed X to be an unbiased estimate X^* . We shall also assume that the error of measurement v is uncorrelated with any of the Z_i (u and w meeting this requirement by construction). Neither of these assumptions is essential for present purposes, though they simplify the presentation, and we shall consider later some of the implications of relaxing them.

Equations (15, 1-3) thus constitute a simultaneous system in which V^* and X are, in effect, endogenous variables, and the Z_i are exogenous variables. It follows then that if we attempt to fit by direct least squares the single equation,

$$(16) \quad V^* = aX + \sum_{i=1}^m b_i Z_i + u',$$

in which V^* is regressed on the Z_i and the endogenous, measured earnings X , the error term u' will not be independent of X , and the coefficients of (16) will be subject to the equivalent of the familiar simultaneous equations bias. More concretely, it can readily be shown (see, e.g., Chow [3, esp. pp. 94-98]) that in the limit for large samples the coefficient of X will be given by

$$a = \alpha \frac{\sigma_w^2}{\sigma_w^2 + \sigma_v^2},$$

which is less than the true value α , and the more so, the larger the variance of the error of measurement σ_v^2 , and the better the included exogenous variables are as proxies for earnings (i.e., the smaller the value of σ_w^2).²⁶ As for the other variables, the coefficients will be given by

$$b_i = \beta_i + \gamma_i \alpha \frac{\sigma_v^2}{\sigma_w^2 + \sigma_v^2} = \beta_i + \gamma_i [\alpha - a]$$

and thus may be larger or smaller than their true values β_i , depending on the direction of correlation with X^* (i.e., on the sign of γ_i).^{27,28}

²⁶ The above expression for the bias in the earnings coefficient was derived on the assumption that (16) was fitted *with* a constant term. If the equation were fitted without a constant term (and if, as we have assumed, there is no constant term in the true specification), then the apparent bias would be considerably smaller. The reason is, of course, that the bias, by flattening the slope of the regression, tends to produce a positive intercept even where none really belongs. Hence forcing the regression through the origin and eliminating the artificial intercept offsets some of the distortion. The offset is only partial, however, and forcing the regression through the origin cannot be regarded as a satisfactory substitute for the more elaborate methods for eliminating the bias to be introduced below.

²⁷ Note that even if some $\beta_i = 0$ (implying that the corresponding Z_i really has no effect on market value), its estimate b_i might still be positive if $\gamma_i > 0$, and that b_i might be quite large if γ_i is large and if the measurement error in X is substantial (so that a is considerably smaller than α). This is, of course, precisely the "information effect" or proxy variable bias we were concerned about in connection with the dividend variable (cf. above, Section II.E and see also the discussion in our [16]).

²⁸ In the light of the system (15) it is interesting to re-examine the problem of bias in the yield-form equations (cf. Sec. II.A). Using the notation above, but interpreting the variables as undeflated, the proposed yield equation becomes

C. An Instrumental Variable Approach

Recasting the original structure in the form (15) not only serves to clarify the nature of the biases introduced by errors of measurement, but also to suggest a remedy, namely an instrumental variable approach. For reasons of computational simplicity as well as ease of interpretation in the present context, we shall implement this approach by means of a two-stage procedure formally equivalent to the two-stage least-squares method of Theil [21]. See also [13]. Operationally, this means first regressing the endogenous variable X on all the instrumental variables Z_i , thereby obtaining estimates g_i of the coefficients γ_i in (15.3). From these estimates a new variable \hat{X} is formed, defined as

$$\sum_{i=1}^m g_i Z_i,$$

and thus constituting an estimate of X^* from which, if our assumptions are correct, the error of measurement v will have been purged.²⁹ If \hat{X}

$$(17) \quad \frac{X}{V^*} = \frac{1}{\alpha} - \frac{1}{\alpha} \sum_{i=1}^m \beta_i \frac{Z_i}{V^*} + u'',$$

where

$$u'' = \frac{v - \frac{1}{\alpha} u}{V^*}.$$

Under our assumptions (a) that X is an unbiased estimate of X^* , and (b) that v is uncorrelated with the Z_i , the measurement error v leads to inefficiency, but not to bias since that error is independent of the explanatory variables. The trouble comes rather from the fact that the endogenous variable V^* is now included among the explanatory variables, thereby leading to a lack of independence between the error term u'' and the variables Z_i/V^* . Thus, the nature of the bias is different when the form of the equation is changed; but given the fact that we have two endogenous variables, bias in one form or another is bound to arise under any single-equation approach.

²⁹ That is, (15.2) and (15.3) imply

$$X = \sum_{i=1}^m \gamma_i Z_i + v + w$$

so that

$$\hat{X} = \sum_{i=1}^m \gamma_i Z_i = X - v - w = X^* + v - v - w = X^* - w,$$

the v term being eliminated. The additional error term $-w$ causes no problems (other than loss of efficiency) since by construction w is orthogonal to all the Z_i and hence to \hat{X} . In practice, of course, we do not know the γ_i exactly but only the regression estimates of them,

g_i . Hence, in defining \hat{X} as $\sum_{i=1}^m g_i Z_i$, there is another error term of the form $\sum_{i=1}^m (\gamma_i - g_i) Z_i$,

which will, however, tend to approach zero as the sample size increases.

is then used in the second stage as the earnings variable in (16) in place of X , (and if the conditions for identification are met) the resulting estimates a and the b_i can be shown to be consistent estimates of α and the β_i in the basic structural equation (15.1).

As for the specific exogenous or instrumental variables to be used we have already considered two, growth and size. In addition, if the coefficients in (16) are to be identified, we must find at least one more such variable that may properly be included in the first-stage regression of X on the Z , and properly be excluded from the second-stage equation (16). We say at least one more because while even a single such variable will suffice for identification, additional variables, by actually overidentifying (16), will help to reduce the loss in the efficiency of estimation—that loss being the price we normally have to pay for gaining consistency by using an instrumental variable approach. In concrete terms, what we need are, of course, variables that can be expected to be strongly correlated with (and hence to convey considerable information about) X^* and, at the same time, to be uncorrelated with the error of measurement in X .³⁰ Fortunately, in the present context, we have a number of likely candidates readily at hand.

The obvious first choice as an instrumental variable for long-run expected earnings is, of course, total assets. This will not provide a perfect measure since the rate base for regulation is not quite the same as total assets and since the allowable rate of return on the base varies somewhat from state to state. Given the fact of regulation, however, and the (partly consequent) substantial uniformity of accounting conventions in the industry, the amount of information conveyed by total assets is still substantial, and certainly far more so here than for virtually any other industry. Note, incidentally, that the fact that all our variables are deflated by total assets creates no particular problem. We can, in effect, incorporate total assets in the first-stage regression by the simple expedient of fitting it with a constant term.

Another presumably very powerful instrumental variable for the net profit component of total earnings would be current dividends paid. As has been stressed here at several points, the practice of dividend stabilization—and the utility industry is the *locus classicus* of such policies—means that dividends and dividend changes indirectly convey a considerable amount of information at least about management's expectations of long-run future profits. In fact, it will be recalled, it was precisely because they conveyed so much information that we were led to omit dividends entirely from the basic valuation equation in order to

³⁰ The second requirement is important, of course, because to the extent that v is correlated with the Z , part of the measurement error will remain in \hat{X} . In fact, if the correlation is very strong, \hat{X} will be little different from and hence little better than X itself.

avoid hopeless confounding of the real and the purely informational effects. The instrumental variable approach thus permits us to break this impasse and to salvage at least some of the informational content of dividends.³¹

For the interest component of expected earnings, it might be thought that the reported figure would be sufficiently close to the true value so that no specific instrumental variable need be introduced on this account. A glance at the accounting statements, however, will show that even interest paid is not an unambiguous concept in the utility industry (nor are the accounting practices completely uniform from company to company, particularly in such matters as the treatment of interest on construction and the separate reporting of interest on short-term obligations). There is the further difficulty that some companies may have issued (or retired) bonds during the year with the result that the reported interest payments for the year represent less than a full-year's interest obligation on the debt outstanding at the end of the year (or more than the future level of obligations in the event of a retirement). Accordingly, an instrumental variable may well prove worthwhile for interest and preferred dividends with the natural choices being the market value of the debt and of the preferred stock. Inclusion of these capital structure variables has the further advantage of picking up any systematic correlation between leverage and the level of total earnings as might arise, for example, if regulatory commissions, as has been suggested, attempt to pass the tax savings from interest deductions forward to consumers by lowering rates.

Though the variables described above would seem adequately to meet the first requirement for good instrumental variables—namely that they be correlated singly and in combination with the unobservable market expectations of normal earnings—we can, of course, never be entirely sure that they also meet the second test—namely that they be uncorrelated with the error in measured earnings. Actually, this independence condition cannot be met literally and exactly. A transient upward fluctuation in current measured profits, for example, must show up either in temporarily higher dividends, or more likely in a level of total assets higher than it otherwise would have been. But while complete independence is not to be expected, we would doubt that such

³¹ It may seem strange at first glance to treat dividends as an exogenous variable in an equation "explaining" X^* when the causation clearly runs from X^* to dividends as a matter of business policy. The fact that dividends may be an endogenous variable from the standpoint of some larger system creates no serious problem at this point, however, since the only use here made of the coefficients in the first stage is in building up an \hat{X} from which the measurement errors in X have been purged. As long as this is accomplished by the first-stage variables taken as a set, the individual coefficients are of little moment. Eventually, of course, when we attempt to put bounds on the effects of dividends on value, we shall have to face up to the endogenous nature of dividends. See below, Section III.E.2.

correlation as does exist is so large as to dash all hopes for substantially improving the estimates by the instrumental variable procedure.

III. *The Results*

A. *Definitions of the Variables*

Before presenting and discussing the results in detail, some brief remarks may be in order with respect to the precise definitions of the variables. Measured, tax-adjusted earnings can be derived from published accounting statements either (a) by means of the formula $\bar{X}(1-\tau)$ where \bar{X} is total before-tax earnings, and τ is the marginal corporate tax rate of 52 per cent in the sample period; or (b) from the formula $\bar{X}'-\tau\bar{R}$, where \bar{X}' is after-tax earnings, and \bar{R} is expected interest payments (cf. n. 8). If tax liabilities were exactly equal to 52 per cent of profits as reported to the shareholders, the two concepts would, of course, be identical. In practice, however, profits as defined for tax purposes do not in general coincide with those reported to the public and the consequent discrepancy between measures (a) and (b) is large enough to force a choice to be made.

It is difficult on purely a priori grounds to establish a decisive case for either alternative. Measure (b) has perhaps an advantage in that reported \bar{X}' is the concept of earnings in terms of which the "reasonable return" is defined by the regulatory commissions. In addition, measure (b) permits an exact derivation of regression equations describing the valuation of shares from those in terms of the value of the firm as a whole—a property that is of considerable value for constructing tests of conflicting hypotheses about the influence of leverage on valuation. Since it also happens to be the case that measure (b) is consistently and substantially the better of the two by the goodness-of-fit criterion, that measure will be used here throughout, and tax-adjusted earnings will thus be estimated as $\bar{X}'-\tau\bar{R}$.³²

In building up our measure of tax-adjusted earnings from the accounting statements we have taken from *Moody's Utilities* the current-year figures for net profits, preferred dividends, and interest paid as defined by the companies themselves. Initially, when we first recognized the seriousness of the errors of measurement problem we experimented with a number of alternative concepts of earnings (e.g., adding back to profits any allocations to a reserve for deferred taxes). None of these concepts, however, appeared to be better than the actually reported current earnings in the sense of yielding consistently higher gross and

³² In terms of the numerical results, the main difference between the two measures is that measure (a) turns out to yield somewhat lower estimates of the cost of capital. In all other respects, however, such as the contributions of the other variables, the behavior of the systems over time and the results of various tests applied to check the specification, the two measures, insofar as we have tested them, give an essentially similar picture.

net correlations with V or of showing less evidence of attenuation in direct least-squares regressions. The same was true, moreover, for simple equally weighted two- and five-year averages of past reported earnings. The relatively poor performance of such averages is probably a reflection of the fact that in the utility industry, the purely "transitory," random components in earnings tend to be quite small relative to the "permanent" shocks (such as those induced by changes in regulation policies or in accounting conventions). Where such is the case, it might well be that some *unequally* weighted average with high weight on the current year probably exists that would do better than either current earnings alone or a simple average. We have, however, made no further attempts to find such an average because there is no real hope that even such an improved measure would be sufficiently error-free to permit dispensing with the instrumental variable procedure. At best there might be a small gain in efficiency, but the eventual second-stage estimate is unlikely to be very different. For simplicity, therefore, we chose to work with current-year earnings (though, once again, this is not a procedure we would recommend for other industries, particularly those subject to cyclical fluctuations in earnings).³³

Another troublesome variable offering several possible choices of definition is the debt variable. Originally, we had thought we could focus exclusively on long-term debt, ignoring short-term liabilities most of which would presumably be noninterest bearing and which, in any event, we expected to be small and relatively uniform throughout the industry. The major definitional problem would then be that posed by convertible issues selling at a substantial premium. As it turned out, however, such issues were quite unimportant during our sample period; but short-term liabilities proved to be both highly variable and in some cases very large in relation to total liabilities. In part, at least, this variation seems to stem from the practice of many companies of financing construction with short-term bank loans that are later refunded after completion of the project. Since it was not always possible to

³³ The main danger in using current earnings arises from the possibility that because of, say, industry-wide strikes or cyclical disturbances, current earnings may be a systematically biased estimate of long-run earnings throughout the industry as a whole. That is, in terms of the system (15), the second equation would have to be replaced by $X = \lambda X^* + v$, $\lambda \neq 1$, implying in turn that the ultimate second-stage estimate of α will be a biased one—yielding α/λ rather than α . Where such industry-wide distortions are present, an average of past earnings will be a less biased measure of X^* and should be used in the first stage even in the unlikely event that it did not perform as well as current earnings in the direct least-squares regression of V on X . In our industry, it happens that the sample mean (deflated) current earnings are so close to the sample mean average earnings that nothing much would be gained in using the average. This is not to say, of course, that either current earnings or average earnings constitute an unbiased estimate of X^* . We suspect that there probably is some (slight) systematic understatement of earnings in both cases due to the more generous depreciation allowances permitted for tax purposes during the Korean War (and by the Revenue Act of 1954) and reflected in profits, either directly or indirectly, via the reserve for deferred taxes.

separate out such loans from other short-term liabilities, the safest course seemed to be to include all short-term liabilities as well as long-term liabilities in the debt variable. Any errors that this approach may involve are not likely to create serious difficulties for present purposes of estimating the cost of capital.³⁴

Debt, preferred stock, common stock and their sum, total value of the firm, are taken at market values and are based on price quotations as of the end of each sample year. To iron out any purely short-term randomness in the price quotations, a simple average of December and January weekly closing prices was employed. The necessary price quotations were always available for common and preferred stock issues, but not always for long-term debt issues where an issue was privately placed and held. In such cases, we estimated the market value on the basis of the yields reported by *Moody's* for comparably rated issues of equivalent term. For the short-term liabilities, we had, of course, no choice but to use the book value of such liabilities. Our measure of V , therefore, must certainly be regarded as subject to error. But there is no reason to believe that these errors (plus the inevitable purely clerical errors) are of a sufficiently systematic nature to bias the estimates.

B. *The Single-Equation Least-Squares Estimates*

Turning now to the results themselves, we first present in Table 1 the estimates obtained from single-stage, least-squares regressions using reported current tax-adjusted earnings as the earnings variable.³⁵ If our analysis has been correct, these estimates should display at least the more obvious symptoms of attenuation bias; and a glance at the top panel of the table shows that such is indeed the case. Here the equation has been fitted with a constant term—a specification, it will be recalled, that is equivalent to adding total assets as an explanatory variable in the undeflated equation. These constants are not only significantly positive in two of the three years—on the order of three to four times their standard errors—but are quite large relative to the mean value of the dependent variable, which is approximately .9 in all three years. The effect is particularly marked in 1954, where the value for the constant of .274 would be far too high to be taken seriously as a measure of the true explanatory contribution of total assets to market value if earnings were measured without error.³⁶

³⁴ Even though the debt variable may include random measurement error, the fact that it is incorporated into the dependent variable keeps such errors from introducing any systematic bias in the coefficients of the value equation. Some problems may arise, however, where tests of the specification are involved. See below, Section III.E.1.

³⁵ The means and standard deviations of the major variables along with the matrix of simple correlation coefficients are presented in Appendix B.

³⁶ Just why the measurement error might be higher in 1954 than in either of the two subsequent years is still not entirely clear to us. Possible explanations might be (a) that fundamental

TABLE 1—DIRECT LEAST-SQUARES ESTIMATES WITH MEASURED EARNINGS

^a Constrained to equal zero.

In the bottom panel of the table, we present the results obtained with the same variables but with constant term suppressed. As would be expected (cf. n. 26), the estimates of the capitalization rate are all higher (especially so in 1954). If our analysis is correct, however, they are still somewhat too low, so that still higher values should presumably be found in the second-stage regressions.³⁷

C. The First-Stage Regressions on the Instrumental Variables

Table 2 shows the first-stage regressions of reported earnings on the instrumental variables. To help in interpretation, the results are presented with and without dividends included among the set of instrumental variables. As can be seen from the first panel, total assets appear to convey considerable information about earnings in this industry—the constant terms ranging from just under 4 to just over 7 times their standard errors. Given total assets, moreover, little additional information seems to be provided by the other variables as evidenced by the low values of the multiple correlation coefficient.

The group of regressions in the second panel, which will serve as the basis for the computed earnings variable in most of the subsequent second-stage regressions, involves the full set of instrumental variables including dividends. As expected, the dividend variable makes a very substantial contribution in all three years. In fact, the combination of dividends, debt, and preferred stock now proxies for the earnings stream so well that there seems to be relatively little left for total assets to contribute (especially in 1956 where total assets are completely swamped).

As for the actual numerical values of the coefficients, there is, of course, little point in attempting to interpret them separately. The relevant concern rather must be whether they seem to behave “sensibly”

revisions in the tax law were made in that year by the Revenue Act of 1954, particularly in the important area of depreciation allowances; (b) that earnings in 1954 still reflected to some extent transitory elements stemming from the Korean War and its immediate aftermath; and (c) that for the many companies in our sample that had only relatively recently emerged as separate entities following dissolutions under the Holding Company Act, reported earnings still reflected transients connected with the process of dissolution.

³⁷ For what it may be worth as an aid in judging goodness-of-fit, the table also shows a column labeled “Multiple R ” for the no-constant regressions. The entry was computed according to the usual definition of R (i.e., $1 - R^2$ = the ratio of the residual variance around the regression to the variance of the dependent variable) even though this may lead to nonsense results when the fit is extremely poor (since the residual variance around the constrained regression line may actually exceed the variance of the dependent variable). An alternative and probably more meaningful way of looking at goodness-of-fit with constant suppressed is to ask how well the regression enables us to “predict” the value of the firm. For this purpose we show the adjusted standard error—the adjustment consisting of summing the squared deviations not around the actual sample mean residual but around zero which is the presumed mean if the specification were really correct—and the adjusted error as a per cent of the sample mean value of V/A .

TABLE 2—FIRST-STAGE LEAST-SQUARES REGRESSIONS OF EARNINGS ON THE INSTRUMENTAL VARIABLES
Dependent Variable: $(\bar{X} - \tau\bar{R})/A$

Year	Coefficients of						Mult. R
	Constant	Size $1/A \cdot 10^7$	Growth $\Delta A/A$	Debt D/A	Preferred Stock P/A	Dividends div/A	
1957	.067 (.01)	.0072 (.008)	.030 (.03)	-.041 (.02)	-.022 (.02)		.31
1956	.055 (.01)	-.0021 (.009)	-.009 (.03)	-.010 (.02)	-.011 (.02)		.13
1954	(.01) (.01)	(.0090) (.007)	-.001 (.02)	.010 (.02)	.004 (.01)		.19
1957	.014 (.01)	.0073 (.006)	.055 (.02)	-.066 (.01)	.029 (.01)	1.18 (.16)	.73
1956	-.001 (.01)	-.0009 (.006)	.022 (.02)	.025 (.02)	.040 (.01)	1.29 (.17)	.71
1954	.011 (.01)	.0039 (.005)	.011 (.02)	.019 (.01)	.024 (.01)	.864 (.14)	.64

taken as a whole and here we can derive at least some comfort from the relative stability of the relations over time. There is evidence of drift over time in some of the coefficients; but the key coefficients with one exception (the debt coefficient of 1957) are of the same sign, order of magnitude, and approximate level of significance in all three years.³⁸

D. *The Second-Stage Estimates*

Table 3 presents the second-stage estimates with the earnings variable constructed from the full set of instrumental variables using the regression coefficients in panel II of Table 2. In the upper half of Table 3 the regressions have been fitted with a constant term so as to provide a check on the validity of our specification that the true constant term is zero. Comparison with the corresponding panel of Table 1 shows that the constant term does indeed drop sharply in the two years, 1957 and 1954, for which it was substantial in the direct least-squares regressions. One coefficient changes sign and all three constants are now much smaller than their standard errors.³⁹ We have therefore considerable support for our hypothesis that the true constant term is zero; and that the large positive constants of the direct least-squares regressions are simply a reflection of the proxying power of total assets when earnings are measured with error. Further confirmation of the errors model (as well as of our conjecture that the errors of measurement in earnings would not be strongly correlated with our instrumental variables) is

³⁸ Although the coefficients in the second set of regressions in Table 2 are relatively stable over time, considerable difference exists between the two sets in the values of the coefficients, particularly of debt and preferred stock. There is, however, nothing anomalous or surprising in these differences. With dividends excluded, the debt and preferred coefficients in the first set show the effects on total earnings of differences in debt and preferred *given total assets*, i.e., essentially the effects of differences in "capital structure." With dividends included, and the constant term close to zero, the debt and preferred coefficients in the second set are largely showing the effects of differences in debt and preferred *given net profits*, i.e., essentially the proxying power of debt and preferred for their corresponding pieces of the income stream.

³⁹ Since no "canned" two-stage least-squares computer program was available to us at the time the estimates were made, the coefficients appearing in Table 3 (and in all subsequent second-stage tables) were computed literally in two stages. That is, a new earnings variable was actually constructed from the first-stage regressions and the second-stage regression run with that variable included among the independent variables. The coefficients so obtained are, of course, exactly the same as those that would have been obtained from a 2SLS program, but that is not true for the standard errors of the coefficients (or the standard error of the regression). In terms of previous notation, the sampling variances in the literal second stage will be the product of the inverse of the moment matrix and the scalar $\text{Var}(u + \alpha w)$; whereas the appropriate scalar multiple for our specification should be $\text{Var}(u - \alpha w)$. An estimate of the latter is provided by the residual variance of the direct least-squares equation recomputed with the 2SLS coefficients. In those cases in which the constant term in the regression is suppressed the desired residual variance must, of course, be computed around the presumed mean of zero under the specification, rather than around the actual sample mean residual. We are grateful to Albert Madansky for some helpful discussion on these and certain related points.

^a Constrained to equal zero.

^b From Panel II of Table 2.

provided by the behavior of the earnings coefficients, all of which are higher than their counterparts in Table 1—particularly so in 1954 where the coefficient increases by nearly 40 per cent.

The second part of Table 3 shows the second-stage regressions with constant term constrained to equal zero. Since the a priori value of the constant term in our model is zero and since the actual sample values, as we have seen, do not differ significantly from zero, these constrained estimates are the most efficient obtainable under our specification. Notice that the loss of efficiency from the use of instrumental variables turns out to be relatively small. In the second-stage regressions, the standard errors of the coefficients average only about 3 per cent higher than those of the direct least-squares regressions.⁴⁰ As it turns out, the earnings coefficients also show only a very slight increase over those in the corresponding part of Table 1. This is, of course, not entirely surprising. Since the bias due to measurement error takes the form of an attenuation of the coefficient of the "noisy" earnings variable, the mere act of suppressing the constant will, as noted earlier, automatically force that slope much closer to its "true" value. Only where the error of measurement is large, as it appears to be in 1954, or where one or more of the other explanatory variables in the equation are strongly correlated with the unobservable X^* are the effects of removing the bias likely to stand out sharply. In our present specification it happens that the other variables are not good proxies for earnings; but, as we saw in the case of the constant term and as we shall see even more strikingly in the next section, such proxies and consequent dangers of bias do enter as soon as we try to test the validity of that specification.⁴¹

E. Some Further Tests of the Specification

1. *Debt and valuation.* It will be recalled (see Sec. I. C) that under our model the value of the firm, growth aside, is equal to capitalized tax-adjusted earnings plus τ times the market value of the debt. Since the coefficient of the debt variable is thus specified to have the value τ independent of the other coefficients, we have so constrained it in all the regressions by subtracting τD from V in forming the dependent variable. For most finance specialists, however, this will be regarded as a gross misspecification. The traditional view in finance has long been that

⁴⁰ It may perhaps be worth mentioning that in terms of their ability to explain V —one measure of this ability being indicated by the relative standard errors shown in the last column of Table 3—the second-stage results here presented compare favorably with those obtained in other valuation studies such as, e.g., Gordon [7].

⁴¹ As a further check on the earnings coefficient, and in particular to see whether our use of dividends as an instrumental variable might be introducing some distortions, we ran the second-stage regressions with \hat{X} constructed from the first panel of Table 2. The earnings coefficients turned out to be almost identical to those in Table 3, but, of course, the standard errors were considerably higher. We also have run the entire set in undeflated form and again found no significant change in the coefficients.

because of the supposed nontax advantages of leverage the contribution of debt to value, given tax-adjusted earnings, will be significantly greater than r ; and that there will also be a substantial positive leverage contribution from preferred stock (whose coefficient, of course, we have in effect constrained to be zero by omitting any preferred stock variable in the value equations). A complete test of these conflicting views about the effects of leverage on valuation would be far too space-consuming for this paper. We shall, therefore (albeit somewhat regretfully), have to postpone any full-scale attempt to settle the leverage issue to a subsequent paper. Fortunately, however, there is no need for present purposes to have the most precise estimate possible of the leverage effect. At the moment, the concern is merely whether our specification is a sufficiently accurate first approximation for purposes of estimating the cost of capital; and this more narrow question can be answered by the relatively simple expedient of including debt and preferred stock among the independent variables and seeing whether they make any significant additional contribution.

The results of this test are presented in Table 4. The top panel shows the direct least-squares estimates using measured earnings. Clearly, if these results were to be taken seriously, our specification would have to be rejected. In one of the three sample years, 1954, the preferred stock coefficient is positive and one and one-half times its standard error, while the debt coefficient is positive and slightly greater than three times its standard error. Taking the three years as a whole, the average debt coefficient is about .13 and the average preferred stock coefficient about .07—values uncomfortably far from zero in the present context. Note also that including these capital structure variables completely reverses the time pattern of the key earnings coefficients with the values increasing steadily from 1954 instead of decreasing as in the second panel of Table 1 or as in Table 3.

Previous results and analysis, however, would lead us to suspect upward bias in these coefficients, particularly in 1954. If the measurement error in 1954 earnings is really as serious as it seemed to be in earlier tests, the proxying power of debt and preferred stock for their corresponding components of the true earnings stream could easily produce positive values as large or larger than the coefficients actually observed in the DLS equation. A glance at the two-stage results in the second panel of Table 4 strongly suggests that such proxying is very definitely at work in the DLS equations. Notice that all six coefficients fall in size—the fall being particularly dramatic in the case of the large debt coefficient of 1954. The average of the three debt coefficients is now only .01 and the average of the preferred stock coefficients a little over .025. The average standard error is many times as large and the coefficients themselves vary unsystematically in sign and magnitude over the

^a Constant constrained to equal zero.

^b Earnings constructed from Panel II of Table 2.

three years. We clearly, therefore, have considerable support for the proposition that we are seeing here only sampling fluctuations around a true value of zero; and that the coefficients of these variables may safely be constrained to zero in the interests of increasing the efficiency of the estimate of the key earnings coefficient.^{42,43}

2. *Dividends and valuation.* The treatment of dividends so far in this paper has been predicated on the assumption that the true, as opposed to the purely informational, effect of dividends on market value is small enough in this industry to be safely ignored. By safely ignored we mean both that it would not be worth the bother to introduce payout terms in the expression for the cost of capital; and that there is no significant loss in the efficiency of estimation of the key earnings coefficient by omitting dividends entirely from the value equation. The two-stage, instrumental variable approach permits us to test these suppositions and in the process to shed some new light on the long-standing controversies in the field of finance over the role of dividends in valuation.

The dividend variable to be used in the tests will be of the form

$$\left(\frac{div}{A} - \lambda \left(\frac{\bar{X}^r - \tau \bar{R}}{A} \right) \right),$$

where λ is the sample average "payout" ratio in terms of $(\bar{X}^r - \tau \bar{R})$ for the year in question. This payout form for the dividend variable has the advantage of preserving the interpretation of the earnings coefficient as the capitalization rate for companies following an average dividend policy and thereby facilitating comparisons with previous results.⁴⁴

⁴² It should be noted, in this connection, that the debt and preferred stock coefficients are likely to be somewhat biased upward even in the second-stage regressions. The bias arises from the fact that we now have the debt and preferred variables on both sides of the equation so that any errors of measurement or of concept will be positively correlated.

⁴³ Once again, we checked to make sure that this result was not somehow an artifact stemming from the use of dividends as an instrumental variable by running the same test with \bar{X} computed from the first panel of Table 2. The general picture was very similar to that in Table 4 with the coefficients of debt and preferred actually averaging even closer to zero. Essentially the same was also true for tests run in undeflated form.

⁴⁴ If div/A is used as the dividend variable, the earnings coefficient measures instead the effect of an increase in earnings, dividends held constant (i.e., of an increase in earnings all of which is retained). The coefficients of the two regressions

$$\frac{V - \tau D}{A} = a_1 \left(\frac{\bar{X}^r - \tau \bar{R}}{A} \right) + a_2 \left(\frac{div}{A} \right) + \dots$$

and

$$\frac{V - \tau D}{A} = a_1' \left(\frac{\bar{X}^r - \tau \bar{R}}{A} \right) + a_2' \left(\frac{div}{A} - \lambda \frac{\bar{X}^r - \tau \bar{R}}{A} \right) + \dots$$

are, of course, not independent and in fact it can easily be verified that $a_2' = a_2$, $a_1' = a_1 + \lambda a_2$, $\text{Var}(a_2') = \text{Var}(a_2)$, and $\text{Var}(a_1') = \text{Var}(a_1) + \lambda^2 \text{Var}(a_2) + 2\lambda \text{Cov}(a_1, a_2)$.

Note also that the optimal value of λ to use would be the regression coefficient of dividends on earnings with all the other explanatory variables included in the regression. Since a constant

The results of the tests are presented in Table 5. The top panel shows the direct least-squares results with measured earnings as the earnings variable. Notice that the dividend coefficient is positive in all three years and very substantially so relative to its standard error and to the earnings coefficient in 1954. Findings of this kind (which are quite typical of past valuation studies) have been the main empirical support of the traditional view that high dividend payouts increase the value of the firm.⁴⁵ If our analysis is correct, however, these coefficients are biased upwards because of the additional information that dividends convey about expected future earnings beyond that contained in the imperfectly measured earnings variable.

The second-stage results in the bottom panel of Table 5 provide a test of this interpretation. Since dividends are included among the instrumental variables, the coefficient of the dividend variable in the second stage should provide an estimate of the contribution of dividends to valuation that is presumably less seriously contaminated by the mere informational effect. In this light the results are quite striking. In each of the three years the point estimate of the coefficient is now found to be negative, although of small magnitude and significance, except possibly in 1954. Thus, at least for this industry in these years the traditional view that the market valuation of shares tends to increase with the proportion of income paid out as dividends is completely unsupported.⁴⁶

term is not included among these other variables, the regression coefficient can be counted on to be extremely close to the mean value of $div/\bar{X}^* - \tau\bar{R}$ and accordingly, for simplicity, we have used these means in the tests presented.

⁴⁵ Since the conventional tests in the literature involving the regression of some value variable (usually share prices) on earnings and dividends do not suppress the constant term, we reran all the DLS equations in Table 5 with constant included to see whether that would make any significant difference. It didn't.

⁴⁶ We can see, however, some possible mechanisms that might lead to a negative bias for the dividend coefficients under the two-stage approach. Consider, for example, the case of a company whose payout ratio is substantially greater than the average for the industry as a whole. Then since dividends enter the first-stage regression with substantial positive weight, the computed value of \hat{X} for that company will tend to be pushed above its measured X and probably also its true X^* . Hence, in the second stage the value of V predicted from \hat{X} will tend to be too high; and since this positive deviation will be associated with above-average dividends, the dividend coefficient will tend to be pushed down so as to reduce the size of the over-all residual. There will, of course, be a similar negative twist imparted to the dividend coefficient in the opposite case of payouts much below the average.

In an effort to determine how important such a bias might be we ran two kinds of supplementary tests. One was a simulation in which the true dividend effect was set at zero and in which about 10 per cent of the firms in the sample were assumed to have payout ratios widely divergent from the industry mean. The result was a very slight negative coefficient, but very far from being statistically significant. The second test consisted of extending the two-stage approach to the dividend variable itself and was motivated, of course, by the fact that the bias described above is closely akin to that occasioned by ignoring the fact that dividends are really an endogenous variable from the standpoint of the system as a whole (cf. n. 31).

^a Constant constrained to equal zero.

^b Earnings constructed from Panel II of Table 2.

For present purposes of estimating the cost of capital, however, perhaps the main conclusion to be drawn from Table 5 is that the dividend effect is sufficiently small and uncertain to be safely neglected. From the statistical point of view the addition of this variable does not appear to improve the reliability of the estimates of the other coefficients, notably that of the critical earnings variable. Indeed, even the small reduction in the residual variability resulting from adding the dividend variable is more or less offset by the loss of one degree of freedom, so that on balance the standard errors of the regression coefficients actually tend to be somewhat higher. And from the substantive point of view, even if one were to accept the coefficients of the dividend variable as a reliable measure of the true dividend effect—which we would certainly hesitate to do in view of the large standard errors and the puzzling drift of the coefficients over time⁴⁷—the implied quantitative effect of dividend policy on market valuation and the cost of capital would still be negligible. In 1954, for example, the year with the largest dividend coefficient in absolute value, the elasticity of the value of the shares at the mean with respect to dividends paid is only about -0.08 . That is, a 20 per cent decrease in dividend payout—which would constitute a very large decrease in this industry, since the standard deviation of the payout ratio is about 10 per cent of the mean—would be associated with an increase in the value of the shares of only about one and one-half per cent, an amount far smaller than the relative standard error of estimate of S itself.⁴⁸ Accordingly, in the discussions of valuation and the cost of capital to follow we shall work exclusively with the results in Table 3 rather than those in Table 5.

Operationally, this meant regressing both X and dividends on the instrumental variables in the top panel of Table 2 and then regressing V on computed X and computed dividends (along with size and growth) in the second stage. The result turned out to be that in all three years the dividend coefficient was less negative than those of Table 5, and in 1957 the coefficient was actually positive and of essentially the same order of magnitude as the direct least-squares estimate. Although these results tend to confirm our suspicions about possible bias of the results in Table 5, we feel they also show that the bias is unlikely to be large enough to force us to revise our conclusion, namely, that the data rule out any substantial positive effect for dividends along the lines of the traditional literature in finance [10, esp. p. 363] or of Gordon [6] or Durand [5]. In this connection, we find it encouraging to note that other researchers are now also beginning to report that the dividend effect is actually relatively small even in the utility industry (see, e.g., Friend and Puckett in [5a] and Beranek [1a]).

⁴⁷ The only plausible rationalization for the drift that we have been able to find is that it may be reflecting the fact that the number of companies paying tax-exempt dividends (cf. n. 19) increased steadily after 1954.

⁴⁸ It may seem strange to some that we test for the effect of dividends on share prices in an equation describing total market value (including debt and preferred stocks) rather than one solely in terms of the value of the common shares. Remember, however, that under our valuation model, the variables debt and preferred stock must be included among the explanatory variables in the S relation (cf. above Sec. I.C). Since these variables are also among the

3. *Comparison with estimates from the yield formulation.* As noted earlier, an alternative way of estimating the cost of capital under our specification would be to use a "yield" equation of the form

$$(18) \quad \frac{\bar{X}r - \tau\bar{K}}{V - \tau D} = a'_1 + a'_0 \frac{1}{V - \tau D} + a'_2 \frac{\bar{\Delta A}}{V - \tau D},$$

with the constant term a'_1 providing the desired estimate of ρ . (Cf. Sec. II.A and n. 28.) The main drawback to this approach comes from the presence of $V - \tau D$ in the denominators of variables on both sides of the equation which imparts an upward bias to the coefficients of the independent variables and a consequent downward bias to the crucial constant term. Since the direction of the bias is known, however, we can use equations of this form to provide at least a rough check on the reasonableness of the estimates obtained by the more roundabout, two-stage approach.

The coefficients obtained in the yield equations are presented in Table 6. To facilitate comparison with the estimates in Table 3 a column has been added showing the reciprocal of the constant term, which is the estimate of the capitalization factor for earnings implied by the observed constant terms in the yield equations.⁴⁹ As predicted under our model, the capitalization factors obtained via the yield equations are indeed all higher than those obtained via the two-stage approach. The gap between the two sets of estimates tends to widen somewhat over time, but the differences are never very large. This close agreement should remove any lingering fears that major distortions in the estimates may somehow have been introduced in the two-stage approach.⁵⁰ At the same time, it suggests that the simpler yield equations may still have

instrumental variables, a second-stage S equation containing computed profits, debt, preferred and dividends would be just identified and that only by virtue of the constant term included in the first stage but suppressed in the second. Since, as we have seen, the contribution of total assets as an instrumental variable is very small when dividends are included (along with debt and preferred) computed profits will be so nearly a linear combination of the other explanatory variables that no effective identification is possible. This extreme collinearity is avoided in the V tests, of course, since debt and preferred are excluded from the V equation along with the constant term. There is some possibility of success in designing dividend tests in terms of S by the use of more elaborate kinds of instrumental variables; but further discussion of these is best postponed to sequel papers. Note also that the practical necessity of excluding at least two of the instrumental variables in order to obtain adequate identification explains why we have not been able to obtain any joint tests of the various specification restrictions considered above singly.

⁴⁹ It can be shown (see Cramér [4, pp. 353-54]), that given a sample estimate \hat{a} with standard error σ , the corresponding (large sample) estimate of $1/a$ is $1/\hat{a}$ and of its standard error, σ/\hat{a}^2 .

⁵⁰ Initially we thought it might be possible to provide further tests of the specification by exploiting the information in the residuals of the estimating equations. For each sample

TABLE 6—DIRECT LEAST-SQUARES ESTIMATES FROM YIELD-FORM EQUATIONS

a useful role to play in valuation studies, particularly where the interest is mainly in determining the direction of changes in the cost of capital over time rather than developing precise estimates or testing the basic specification as developed here.

F. Summary

In this section we have attempted to apply and to test the model of valuation developed in Sections I and II of this paper. Strong support has been presented for our contention that the usual direct least-squares value equations (and yield-form equations) lead to biased estimates of the key parameters. The evidence has also been seen to be consistent with our specifications with respect to the constant terms, the value of the debt coefficient and the role of dividends. Given these specifications, the most efficient, consistent estimates of the value relation are those shown in the second panel of Table 3; and it is to the economic interpretation of these results that we now turn.

year we have three residuals which can be expressed in previous notation as $u_{1t} = u_t - \alpha v_t$, $u_{2t} = u_t + \alpha_1 w_t$, and $u_{3t} = v_t + w_t$. If, therefore, we could assume $E(u_t v_t) = E(u_t w_t) = E(v_t w_t) = 0$ for $t, \tau = 1957, 1956$, and 1954, we could obtain estimates of the variances of the specification and measurement errors for each year as well as of the interyear correlations of the specification and measurement errors. As it turns out, however, the assumption that the side correlations are zero is clearly untenable (there being particularly strong evidence of substantial negative correlation between v and w).

Although the residuals thus cannot be exploited to get directly at the specification error, the question arises as to whether they can at least be exploited to improve the efficiency of the estimates of the coefficients along the lines suggested in Zellner and Theil [23], Zellner [22], or Telser [20]. Even if there were no conceptual difficulties in applying these methods to models involving measurement error it seems very doubtful that the gain in efficiency would be worth the cost in our case because of the very high year-to-year correlation between the independent variables.

TABLE 7—SOURCES CONTRIBUTING TO THE VALUE OF THE FIRM

IV. Valuation and the Cost of Capital in the Utility Industry

A. The Anatomy of Valuation

In Table 7 the coefficients from Table 3 have been multiplied by the sample mean values of the variables so as to illustrate the relative importance of the various factors contributing to the market value of the typical firm in the industry. As expected, by far the largest component of market value is the capitalized earning power of the assets currently held. Next in importance is the tax subsidy to debt reflecting, of course, both the high corporate tax rate during the sample years and the very high debt ratios characteristic of this industry. Future growth potential, though small, was apparently increasing steadily in importance relative to current earning power over this period and by 1957 was accounting for something over 10 per cent of market value. The only mild surprise perhaps is the virtually negligible contribution of size to value. The difference in valuation, other things equal, between a firm of indefinitely large size and that of mean size in our sample turns out to be only on the order of 1 or 2 per cent of total market value. It should be remembered, however, that by ordinary standards, *all* the firms in our sample are extremely large.⁵¹

B. The Cost of Equity Capital

Turning now from valuation to the other side of the coin, the cost of capital, we show in Table 8 the estimates of the cost of equity capital implied by the earnings coefficients of Table 3.⁵² For comparison, the table also shows two other measures of the cost or "ease of acquisition"

⁵¹ To see whether a more direct size variable than our $1/A$ might lead to different results we reran the equations using $\log A$ as the measure of size (in the deflated equations). No significant change occurred either in the relative importance of the size effect or in the values of other coefficients.

⁵² Cf. note 49.

TABLE 8—ESTIMATED COST OF EQUITY CAPITAL AND SOME ALTERNATIVE MEASURES OF EQUITY COSTS

Year	Estimated Cost of Equity Capital (ρ)		Average Earnings Yield on Shares ($\bar{\pi}/S$)		Reciprocal of Price to Book-Value Ratio (B/S)		Average Tax- and Leverage-Adjusted Total Earnings Yield $(\bar{X}^T - \tau\bar{R})/(V - \tau D)$	
	Amt.	As per cent of 1954	Amt.	As per cent of 1954	Amt.	As per cent of 1954	Amt.	As per cent of 1954
1957	.062	122	.070	106	.64	105	.056	110
1956	.060	118	.070	106	.63	103	.056	110
1954	.051	100	.066	100	.61	100	.050	100

of equity capital frequently used by economists in investment studies, namely, the average earnings-price ratio and the reciprocal of the average price-book value ratio for the shares. Notice that all three measures indicate a rise in the cost of equity capital between 1954 and 1957, but our measure indicates a steeper and more substantial increase over the interval. The causes and implications of this apparently lesser responsiveness of the standard measures will become clear in subsequent discussion.

Insofar as levels are concerned, notice that the average earnings yield happens to be consistently higher than our estimate of the cost of equity capital. We say "happens to be" to emphasize that under our model of valuation there is no "normal" or even simple relation to be expected between the two concepts. The earnings yield for any company is not a given fixed number for each member of the class, as so much of the traditional discussion in finance and economics would suggest, but rather a function whose arguments include the cost of equity capital for the class, the firm's growth potential, its leverage policy, and its size. The sample mean earnings yield shows only the combined effect of these different and to some extent offsetting influences.

The precise way in which the various components of the yield fit together in the present sample is illustrated in Table 9. The entries have been computed by "solving" our fitted V equations for their implied $\bar{\pi}/S$ functions, and then substituting the appropriate sample mean values for the variables into these derived functions. Specifically, if the V equation (neglecting the deflator) is represented as

$$(19) \quad V - \tau D = -a_0 + a_1(\bar{X}^T - \tau\bar{R}) + a_2\Delta\bar{A};$$

then, making use of the identities $V \equiv S + D + P$ and $\bar{X}^T = \bar{\pi} + \bar{P}dv + \bar{R}$, we have as the implied function for the value of the shares (cf. II. C):

$$(20) \quad S = -a_0 + a_1 \bar{\pi}^r - (1 - \tau)[D - a_1 \bar{R}] - [P - a_1 \bar{P} \bar{d}v] + a_2 \bar{\Delta A},$$

and as the implied earnings yield function:

$$(21) \quad \frac{\bar{\pi}^r}{S} = \frac{1}{a_1} - \frac{\left(\frac{a_2}{a_1}\right) \bar{\Delta A}}{S} + \frac{(1 - \tau) \left(\frac{D}{a_1} - \bar{R}\right)}{S} \\ + \frac{\left(\frac{P}{a_1} - \bar{P} \bar{d}v\right)}{S} + \frac{\left(\frac{a_0}{a_1}\right)}{S}.$$

The first term of (21) is the cost of equity capital in our sense for the class as a whole; the second is the growth effect; the third and fourth, the leverage effects for debt and preferred stock, respectively; and the last term is the size effect. The presence of leverage, by raising the "risk" attaching to the shares, drives up the expected earnings yield relative to the cost of equity capital. The existence of growth potential with its implied prospect of future capital gains tends to reduce the current expected earnings yield on the shares.

As can be seen from Table 9, the leverage effect was the dominant one over the period as a whole which, of course, explains why the earnings yield consistently overstated the cost of equity capital during this period. The substantial narrowing of the gap between 1954 and 1957 reflects the large rise in the growth contribution after 1954 both in absolute and relative terms.

C. Valuation, Growth, and the Cost of Equity Capital

Although the conventional earnings/price ratio is thus distorted as a measure of the cost of equity capital both by the growth effect and the

TABLE 9—RELATION BETWEEN AVERAGE EARNINGS YIELD AND THE COST OF EQUITY CAPITAL

Total	.063	.060	.053
Estimated Cost of Equity Capital	.062	.060	.051

leverage effect, it is important to remember that the real culprit is the growth effect. That is, it is the growth effect and not the leverage effect that keeps us from being able to infer the cost of equity capital directly from market yields. We know, for example, that if there were no growth and no taxes the fundamental valuation equation, expressed in yield form, would be simply $\bar{X}/V = \rho$. The ratio of expected total earnings to total market value—which may be thought of as a “leverage-corrected” yield—would thus provide a direct estimate of ρ . In principle, any firm could so approximate its cost of equity capital from its own company data, although, of course, as a practical matter, a better estimate would be obtained by averaging over a large group of similar firms so as to wash out any random noise in \bar{X} or V . When we allow for taxes and the consequent tax subsidy on debt, the picture becomes slightly more complicated, but a direct approximation of ρ still exists. The appropriate yield [cf. (6) above] now becomes $(\bar{X}^* - \tau \bar{R}) / (V - \tau D)$ —the ratio of total tax-adjusted earnings to total market value minus the value of the tax subsidy.

This method of direct approximation breaks down, however, in the presence of growth. The leverage-adjusted yield will be systematically too low as an estimate of ρ for any company with growth potential, as will be the group average yield for any sample that contains significant numbers of growth companies. Nor will the movements of the yield over time conform well with changes in ρ to the extent that the market's evaluation of future growth potential changes over time (and, of course, much of the short-term variation we see in share prices stems precisely from this source). Some idea of how sizable the distortions of level and movement of the yield relative to ρ can be—even in such a low-growth industry as our electric utilities and even over such a short span of time—can be gained by comparing our estimates of the cost of equity capital in the first column of Table 8 with those of the tax- and leverage-adjusted yield, $[(\bar{X}^* - \tau \bar{R}) / (V - \tau D)]$, in the last column of that table.

One somewhat surprising aspect of this comparison that is perhaps worth some special mention is the relative stability of the yield series over this period. Because of the many uncertainties surrounding estimates of future growth potential and because of the sensitivity of current market values to even small changes in projected growth rates one would expect the growth component in the denominator of the yield ratio to be quite volatile; and hence that the market yield would tend to swing quite substantially in response to these continuing re-evaluations. Some idea of why this “normal” pattern did not obtain during our sample period can be gained from Figure 1. The solid line functions there plotted are the basic value regressions of Table 3 for the beginning and ending years, 1954 and 1957, expressed in ratio form as

FIGURE 1

$$\frac{V - rD}{\bar{X}r - r\bar{R}} = a_1 + a_2 \frac{\bar{\Delta A}}{\bar{X}r - r\bar{R}}$$

(and hence ignoring the minor size effect). The dependent variable is thus the reciprocal of the tax- and leverage-adjusted yield; the intercept a_1 is our estimate of $1/\rho$; and the slope a_2 is the coefficient of growth in the V equation.⁵³

Notice that in 1954, at the beginning of the period, the market's estimate of the growth potential of the industry was quite low. Because the slope was so flat, the approximate sample mean value of $(V - rD)/(\bar{X}r - r\bar{R})$ —indicated by the circled cross—differed only very slightly from the estimate of $1/\rho$ implied by the intercept. By 1957, however, a striking increase had taken place in the market's valuation of future

⁵³ The use of the reciprocal of the yield rather than the yield itself is simply a matter of convenience since the presence of growth impounded in V would lead to a nonlinear relation between $(\bar{X}r - r\bar{R})/(V - rD)$ and growth as measured by $\bar{\Delta A}/(V - rD)$.

growth in the industry. As can be seen from the broken line—which has been plotted with 1954 intercept and 1957 slope—this large revaluation would have pushed the average value of $(V-\tau D)/(\bar{X}-\tau\bar{R})$ up by nearly 15 per cent to 22.4 (equivalent to a yield of about .044) if no other changes had occurred. But instead of this “pivoting” around a stable intercept of $1/\rho_{54}$, our estimates indicate that there happened to take place a simultaneous and quite substantial drop in the intercept (i.e., rise in the cost of equity capital). So substantial, in fact (when combined with the slight fall in the mean value of the growth variable itself), that the upward push of the revaluation of growth was more than offset; and the mean value of $(V-\tau D)/(\bar{X}-\tau\bar{R})$ actually fell by about 10 per cent.

Although these compensating movements in ρ and the market's evaluation of growth “explain” the relative stability of the tax- and leverage-adjusted yield during the sample period, the explanation may strike the reader as having a somewhat paradoxical flavor. Growth potential, after all, is the opportunity to invest in the future in projects whose rates of return exceed the cost of capital. One would expect, therefore, that a rise in the cost of capital would normally be associated with a *fall* in growth potential. There are a number of possible explanations for the opposite behavior in the present instance, but discussion of them is perhaps best postponed until we have first provided estimates of the average cost of capital relevant for investment decisions.

D. The Required Yield or Average Cost of Capital

As emphasized earlier, the relevant cost of capital for investment decisions at the level of the firm is the average cost of capital, $\rho(1-\tau L)$, where L measures the “target” proportion of debt in future financing. The average cost is thus not a fixed number, but a schedule or function whose arguments are ρ (which is an “external” property of the class or industry determined by the market) and L (which is a matter of “internal” company policy). Although the average cost of capital, unlike the cost of equity capital, is thus in principle different for each firm in the industry, we can get some idea of its value and behavior for the typical electric utility by using a typical or average value for L . The obvious candidate, of course, is the actual sample average of D/A for each year, since D/A measures the average proportion of debt in past financing, and this proportion is likely to be quite stable (particularly when averaged over the industry). Estimates with these values for L are shown in block 1 of Table 10. (N.B. For notational convenience we shall hereafter refer to these estimates as $C(\bar{D}/\bar{A})$, using $C(L)$ to mean the function itself, and $C(D/A)$, i.e., without the bar on D/A , to refer to

the function evaluated not at the industry mean but at a particular company's value of D/A .)

These estimates $C(\overline{D/A})$ of the average cost of capital are, of course, always below the corresponding estimates of ρ (column 1 of Table 8); but the movements over time of the two series are closely similar since, as expected, the sample mean value of D/A is quite stable.⁵⁴ Notice also that the estimates of ρ and hence of $C(\overline{D/A})$ conform quite closely in their movements with the average yield on AAA bonds in the industry (block 2 of Table 10)—probably the most popular surrogate for the cost of capital in investment studies. This conformity is particularly interesting since the rate of interest on bonds enters only very indirectly into our calculations of ρ and $C(\overline{D/A})$ and, as can be seen from block 3, the implied average rate of interest in our sample does not even seem to conform well with the AAA series.⁵⁵ From the economic point of view, this parallelism between movements in ρ and the AAA yields would seem to suggest that over this short interval at least the movements of both series were dominated by factors affecting the supply of and demand for capital generally. Changes, if any, in investors' tastes for risk-bearing or in their evaluation of the riskiness of this industry in relation to others were apparently not large enough to cause any significant divergence of movement in the period under study.

It is also instructive to contrast our estimates of the average cost of capital with those that would be obtained by following the prescriptions laid down in much of the traditional literature of corporation finance. Essentially, these call for computing the weighted sum of the market yields of each type of security, the weights being the "target" proportions of each security in the capital structure. That is, if we let i = the earnings/price ratio (our $\bar{\pi}/S$); p = the preferred dividend yield (our \overline{Pd}/P); r = the average rate of interest on bonds (our \bar{R}/D); l = the target debt ratio; and l' = the target preferred ratio then the weighted average cost of capital function under the traditional view can be expressed as $i(1-l-l') + p(l') + r(1-\tau)(l)$. Where the target weights l and l' are computed at book value as is usually recommended (i.e., with $l = D/A$ and $l' = P/A$ and $(1-l-l') = B/A$ in our notation) we shall refer to the resulting average as $\bar{C}_B(D/A)$; where they are taken at market value (i.e., with $l = D/V$ and $l' = P/V$ and $1-l-l' = S/V$) we

⁵⁴ In interpreting these estimates of the average cost of capital it may be worthwhile to remind readers that the figures in column 1 represent *tax-adjusted* yields (cf. notes 8 and 11) and are not adjusted for size (i.e., they would apply, strictly speaking, only to firms of infinite size). Adjusting to the average size of firm in our sample and converting to the more familiar *before-tax* basis, the corresponding average costs would be .073, .087 and .090, respectively, for 1954, 1956, and 1957.

⁵⁵ One important reason for the divergence between market rates on bonds and our implied average yields is the fact that our debt variable in the denominator contains substantial and varying amounts of short-term liabilities.

shall refer to the average as $\bar{C}_M(D/V)$, with unbarred values of the argument standing as before for a single company value and barred values for industry means. Estimates of both $\bar{C}_B(D/V)$ and $\bar{C}_M(D/V)$ for the typical firm in the sample, using actual sample mean values of i , p , and τ , as well as of the book- and market-value measures of l and l' in each case, are shown in blocks 5 and 6 of Table 10.⁵⁶

As can be seen from Table 10, both the levels and the time paths of $\bar{C}_B(D/A)$ and $\bar{C}_M(D/V)$ differ significantly from those of $C(D/A)$. The largest discrepancies arise in the case of the widely used $\bar{C}_B(D/A)$ measure which is substantially below $C(D/A)$ in all three years and which shows only a very slight rise over the period. The market value estimates, $\bar{C}_M(D/V)$ are considerably closer to those of $C(D/A)$, but they too fail to indicate the sizable increase in the cost of capital which seems to have occurred during this period.

E. Reconciliation with Conventional Averages

To understand precisely why these three methods of estimating the average cost of capital gave such different answers for the years under study (and why they are likely to continue to diverge for other years and other industries), it is helpful to begin by showing how these estimates would relate to each other in a much simpler world in which no growth potential ever existed. In such a world, we have seen that the ratio $(\bar{X}^r - \tau \bar{R}) / (V - \tau D)$ —the tax- and leverage-adjusted yield of the previous section—would be a measure of our ρ , the cost of equity capital. Hence, from the standpoint of any individual firm, the $C(L)$ function can be expressed as

$$(22) \quad C(L) = \frac{\bar{X}^r - \tau \bar{R}}{V - \tau D} (1 - \tau L) = \frac{\bar{X}^r - \tau \bar{R}}{V} \cdot \frac{1 - \tau L}{1 - \tau D/V}.$$

* An alternative way of computing industry averages would be not to average the product of the mean yield times the mean weight as was done in Table 10, but to average the product of the yield and weight for each company separately. In the case of $\bar{C}_M(D/V)$ this leads to the very simple relation

$$\begin{aligned} \bar{C}_M(D/V) &= \left(\frac{\bar{\pi}^r}{S} \cdot \frac{S}{V} \right) + \left(\frac{\bar{P}d\bar{v}}{P} \cdot \frac{P}{V} \right) + \left(\frac{\bar{R}(1 - \tau)}{D} \cdot \frac{D}{V} \right) \\ &= \left(\frac{\bar{\pi}^r}{V} \right) + \left(\frac{\bar{P}d\bar{v}}{V} \right) + \left(\frac{\bar{R}(1 - \tau)}{V} \right) = \left(\frac{\bar{X}^r - \tau \bar{R}}{V} \right). \end{aligned}$$

The sample values of the latter yield are .038, .043, and .042, respectively, for 1954, 1956, and 1957. The (slight) difference between the two estimates arises, of course, from the fact that the company values of $\bar{\pi}^r/S$ are not independent of the values of S/V , i.e., of the company's degree of leverage.

Note also, for simplicity, we shall here and hereafter ignore the small difference between the book value and the market value of debt and preferred, using the market values in all cases.

The weighted average cost of capital function with market-value weights is

$$(23) \quad \bar{C}_M(D/V) = \frac{\bar{\pi}^*}{S} \cdot \frac{S}{V} + \frac{\bar{P}\bar{d}v}{P} \cdot \frac{P}{V} + \frac{\bar{R}(1-\tau)}{D} \cdot \frac{D}{V} = \frac{\bar{X}^* - \tau\bar{R}}{V}$$

and with the book-value weights,

$$(24) \quad \bar{C}_B(D/A) = \frac{\bar{\pi}^*}{S} \cdot \frac{B}{A} + \frac{\bar{P}\bar{d}v}{P} \cdot \frac{P}{A} + \frac{\bar{R}(1-\tau)}{D} \cdot \frac{D}{A}.$$

Notice first that for the special case of $L = D/V$ —i.e., when the target leverage coincides with current leverage at market value, D/V , the function $C(L)$ takes the value

$$C(D/V) = \frac{\bar{X}^* - \tau\bar{R}}{V} = \bar{C}_M(D/V).$$

In other words, if a firm's current and future target leverage is D/V it will get precisely the same estimate for its average cost of capital regardless of whether it chooses to multiply its current tax- and leverage-adjusted yield by $[1 - \tau(D/V)]$; or to compute the weighted average of the current yields of its outstanding securities, with market-value weights for each; or if it simply uses the ratio of expected tax-adjusted earnings to total market value. A similar equivalence of estimates (at least to a very close degree of approximation) would also hold, of course, for economists concerned with "typical" values for the industry and using industry mean values of D/V and of the various yields, i.e., $C(\bar{D}/\bar{V}) \cong \bar{C}_M(\bar{D}/\bar{V})$.⁵⁷ Note also that if $V = A$ —which would tend to be the case if there were no growth past or future—then $\bar{C}_B(D/A)$ becomes the same function as $\bar{C}_M(D/V)$ and, by extension, as $C(L)$. In this special case of no growth, therefore, all three company and industry-wide estimates will coincide.

This simple picture changes quite drastically, however, as soon as growth potential is introduced. The function $C(L)$ must now be expressed as

⁵⁷ Although the equivalence holds for individual company data and for industry averages, there is one important case in which the equivalence very definitely does *not* hold. This is the common case of the firm following the weighted average approach of (23) with current (or prospective future) company weights, but using industry-wide averages of the component yields so as to obtain less noisy estimates. The trouble here is that the market yield on shares (and to some extent the yields on preferred and bonds as well) are increasing functions of leverage. Hence, for a firm whose target leverage is greater (smaller) than the average for the industry the industry mean yield will be an underestimate (overestimate) of its own yield and the resulting average cost of capital will be too low (high). This problem does not arise under our (22), of course, since $(\bar{X}^* - \tau\bar{R})/(V - \tau D)$ is not a function of firm policy (as is $\bar{\pi}^*/S$), but an estimate of the external, market-given parameter, ρ .

$$(25) \quad C(L) = \frac{\bar{X}^r - \tau \bar{R}}{V - \tau D - G} (1 - \tau L) = \frac{\bar{X}^r - \tau \bar{R}}{V - G} \cdot \frac{1 - \tau L}{1 - \tau \left(\frac{D}{V - G} \right)},$$

where G = the market's current valuation of future growth potential. Hence, as can be seen by reference back to (23), there no longer exists any concept of L for which the function $C(L)$ will be the same as $\bar{C}_M(D/V)$. Note also that in the special case in which future growth potential constitutes the only major source of divergence between V and A , $(\bar{D}/A) \cong [\bar{D}/(\bar{V} - G)]$, so that our estimates of the average cost of capital $C(\bar{D}/A)$ would be closely approximated by the ratio $[(\bar{X}^r - \tau \bar{R})/(V - G)]$. The actual sample mean values of that ratio (with G taken as the product of the growth coefficient in Table 3 and the mean value of our growth variable $\Delta A/A$) are shown in the last block of Table 10. As can be seen, the approximation to $C(\bar{D}/A)$ is indeed quite close in 1956 and 1957; but it is less satisfactory in 1954 where the growth contribution is small both in absolute terms and relative to the other sources of divergence between V and A .

Where the ratio $[(\bar{X}^r - \tau \bar{R})/(V - G)]$ is a good approximation to $C(\bar{D}/A)$, it will, of course, also follow that both measures will exceed $\bar{C}_M(\bar{D}/V)$, which, as we saw above, is given approximately by $[(\bar{X}^r - \tau \bar{R})/V]$. As for the relation between the popular $\bar{C}_B(\bar{D}/A)$ and $C(\bar{D}/A)$ note that we can express the ratio $[(\bar{X}^r - \tau \bar{R})/(V - G)]$ approximately as

$$(26) \quad \left(\frac{\bar{X}^r - \tau \bar{R}}{V - G} \right) = \left(\frac{\bar{\pi}^r}{S - G} \cdot \frac{S - G}{V - G} \right) + \left(\frac{Pdv}{P} \cdot \frac{P}{V - G} \right) \\ + \left(\frac{\bar{R}(1 - \tau)}{D} \cdot \frac{D}{V - G} \right) \cong \left(\frac{\bar{\pi}^r}{S - G} \right) \left(\frac{\bar{B}}{A} \right) \\ + \left(\frac{Pdv}{P} \right) \left(\frac{\bar{P}}{A} \right) + \left(\frac{\bar{R}(1 - \tau)}{D} \right) \left(\frac{\bar{D}}{A} \right),$$

since the assumption $V - G \cong A$ implies

$$\frac{D}{V - G} \cong \frac{D}{A}, \quad \frac{P}{V - G} \cong \frac{P}{A} \quad \text{and} \quad \frac{S - G}{V - G} \cong \frac{B}{A}.$$

Comparison with (24) shows that the weights in the two expressions are essentially the same; but since $(\bar{\pi}^r/S) < [\bar{\pi}^r/(S - G)]$, $\bar{C}_B(\bar{D}/A)$ too will necessarily fall short of $C(\bar{D}/A)$ when growth is present, and the gap will be larger, the larger is the contribution of growth to the value of the shares.

Once again, then, we see that attempts to infer the cost of capital directly from market yields rather than by the more detailed, cross sectional estimating procedures developed in this paper break down in the face of growth. Where growth is present all of the popular, short-cut approximations will underestimate the cost of capital; and, where the market changes its evaluation of growth potential over time (as is inevitable in view of the nature of growth) the time path of the yield measures may give a quite misleading picture of the true changes in the cost of capital. In particular, in our sample it happens that the market's evaluation of growth increased substantially over the period, thereby causing the yield measures to understate seriously the rise in capital costs that appears to have been taking place at the same time. As noted earlier, it is somewhat paradoxical that these two changes should have occurred simultaneously, since an increase in the cost of capital should tend to reduce what the market is willing to pay for given investment opportunities. We can perhaps throw some light on this paradox by taking a closer look at our growth coefficients and their implicit components.

F. *A Further Analysis of the Valuation of Growth*

As noted earlier (cf. Sec. II.E above) the growth term in our basic valuation equation is of the form

$$k\bar{X}(1 - \tau) \left[\frac{\rho^* - C}{C(1 + C)} \right] T,$$

where k is the ratio of investment to tax-adjusted earnings; C = the average cost of capital; ρ^* = the tax-adjusted rate of return on new investment; and T is a measure of the length of time for which the opportunities to invest at the rate ρ^* are expected to last. In the actual estimating equations we have taken as our growth variable an estimate of $k\bar{X}(1 - \tau)$, the level of future investment opportunities. Hence, if one accepts the underlying model, the observed coefficients of the growth variable can be interpreted as an approximation to

$$[(\rho^* - C)/(C(1 + C))]T.$$

Now that we have estimates of C , the average cost of capital for a typical firm, we can attempt some further decomposition of these growth coefficients.

In particular, it should be possible from what we know about past earnings and about the regulatory process governing earnings in the industry to make at least a rough approximation of ρ^* .

An obvious first candidate as an approximation to ρ^* is, of course, the current, tax-adjusted rate of return on assets, $(\bar{X}r - \tau\bar{R})/A$. Such a

TABLE 11—ANALYSIS OF THE GROWTH EFFECT

^c Computed as $G((C)(1+C)/(\rho^*-C))$.

measure, however, is almost certainly an underestimate of ρ^* , since we know that there are components of total assets—actually, of total liabilities—that regulatory commissions systematically exclude from the rate base.⁵⁸ Some idea of the extent of this underestimate is provided by the knowledge that during these years most of the state commissions were still setting the “reasonable return on the rate base” in the near neighborhood of the classical 6 per cent. By contrast, the sample average values of $\bar{X}'/A - \bar{X}'$, rather than $(\bar{X}' - \tau\bar{R})$, being the relevant earnings concept in rate-setting—were only .054, .056, and .055 per cent in 1954, 1956, and 1957, respectively. One simple adjustment, therefore, would be to blow up each sample mean value of $(\bar{X}' - \tau\bar{R})/A$ by the ratio of 6 per cent to the sample mean value of \bar{X}'/A . The rates of return so adjusted, as well as the original unadjusted rates of return, are presented in Table 11 along with the estimates of T they imply.

These results would seem to suggest the following as the resolution of the paradox described in the previous section. The observed rise in the markets' valuation of the industry's growth potential, in the face of the sharp rise in the cost of capital during the period, cannot reasonably be attributed to any compensating increase in the expected rate of return on future investment. No sharp upward trend in earnings rates, adjusted or unadjusted, is visible in the data; nor would such a trend be

⁵⁸ A further word of caution is necessary because the so-called accounting rate of return (earnings after depreciation divided by net assets) is not the same as the ordinary internal rate of return when a firm is growing. This discrepancy does not seem likely to create any very serious problems insofar as the valuation equations or estimates of the cost of capital are concerned since in those equations assets appear only as a deflator and since an explicit growth variable is included. It may, however, raise difficulties for comparisons of the kind being attempted here. We say may, because the ρ^* in our formula is not the usual internal rate of return, but the so-called “perpetual rate of return” (see [14, p. 416]), and the relations between that rate and the accounting rate of return have, to our knowledge, nowhere yet been explored. We are indebted to Sidney Davidson and Robert Williamson for some helpful discussions on this general point.

expected in view of the regulatory controls over the level of earnings. What seems to have been happening rather is that early in the period investors came to recognize that the regulatory authorities were setting rates at levels that would probably permit firms in the industry to earn significantly more than the cost of capital on any new capital invested. The subsequent rise in the cost of capital narrowed the margin of gain somewhat; but its effects on valuation were more than offset by an increase in the length of time that favorable terms for new investment were expected to persist. The actual numerical estimates of this time horizon, as presented in Table 11, are not, of course, to be taken seriously in view of the many approximations, theoretical and empirical involved in their computation. But a general expansion of horizons (or at least an increasing awareness of growth potential on the part of investors) is very definitely indicated.

Conclusion

This has been a long and necessarily somewhat tedious paper, and we do not propose to add either to the length or the tedium by an extensive summary at this point. Instead, we shall simply close by indicating briefly what we believe to be the main conclusions that can be drawn from the material presented. These are:

1. With respect to the methodology of empirical valuation and cost of capital studies, we feel we have demonstrated that the two-stage instrumental variable approach developed here can be an effective way of dealing with the problems caused by errors of measurement of expected future earnings—problems that bear a major share of the responsibility for the meager progress in empirical research on this front to date. We can also report some success in our attempt to provide an explicit measure of growth potential for the utility companies in our sample, but, clearly, more general methods of dealing with this crucial variable are urgently needed before substantial further progress on the cost of capital problem can be made.

2. With respect to the theory of valuation, we found that the rational-behavior, perfect-market model of valuation under uncertainty stands up quite well when confronted with the data both in terms of what it says should be included, and what it says should be excluded. In particular, for the utility industry in these years we found no evidence of sizable leverage or dividend effects of the kind assumed in much of the traditional literature of finance.

3. As for our estimates of the cost of equity capital and of the average cost of capital we showed that they differ very considerably both in level and movement during the sample period from the conventional

kinds of "yield" estimates so widely used in economics and finance. On the other hand, our estimates for the utility industry do seem to conform reasonably closely over the (short) sample period with movements in the long-term rate of interest on bonds. It will be interesting to see whether this relation persists in other industries and over longer and less placid intervals of time.

ALLOCATIVE EFFICIENCY VS. "X-EFFICIENCY"

By HARVEY LEIBENSTEIN*

At the core of economics is the concept of efficiency. Microeconomic theory is concerned with allocative efficiency. Empirical evidence has been accumulating that suggests that the problem of allocative efficiency is trivial. Yet it is hard to escape the notion that efficiency in some broad sense is significant. In this paper I want to review the empirical evidence briefly and to consider some of the possible implications of the findings, especially as they relate to the theory of the firm and to the explanation of economic growth. The essence of the argument is that microeconomic theory focuses on allocative efficiency to the exclusion of other types of efficiencies that, in fact, are much more significant in many instances. Furthermore, improvement in "nonallocative efficiency" is an important aspect of the process of growth.

In Section I the empirical evidence on allocative efficiency is presented. In this section we also consider the reasons why allocation inefficiency is frequently of small magnitude. Most of the evidence on allocative inefficiency deals with either monopoly or international trade. However, monopoly and trade are not the focus of this paper. Our primary concern is with the broader issue of allocative efficiency versus an initially undefined type of efficiency that we shall refer to as "X-efficiency." The magnitude and nature of this type of efficiency is examined in Sections II and III. Although a major element of "X-efficiency" is motivation, it is not the only element, and hence the terms "motivation efficiency" or "incentive efficiency" have not been employed.

As he proceeds, the reader is especially invited to keep in mind the sharp contrast in the magnitudes involved between Tables 1 and 2.

I. Allocative Inefficiency: Empirical Evidence

The studies that are of interest in assessing the importance of allocative efficiency are summarized in Table 1. These are of two types. On the one side we have the studies of Harberger and Schwartzman on the "social welfare cost" of monopoly. On the other side we have a number of studies, among them those by Johnson, Scitovsky, Wemelsfelder, Janssen, and others, on the benefits of reducing or eliminating restrictions to trade. In both cases the computed benefits attributed to the reallocation of resources turn out to be exceedingly small.

*The author is professor of economics at the University of California, Berkeley.

TABLE 1—CALCULATED "WELFARE LOSS" AS PERCENTAGE OF GROSS OR NET NATIONAL PRODUCT ATTRIBUTED TO MISALLOCATION OF RESOURCES

Study	Source	Country	Cause	Loss
A. C. Harberger	<i>A.E.R.</i> 1954	U.S.A. 1929	Monopoly	.07 per cent
D. Schwartzman	<i>J.P.E.</i> 1960	U.S.A. 1954	Monopoly	.01 per cent
T. Scitovsky	(1)	Common Market 1952	Tariffs	.05 per cent
J. Wemelsfelder	<i>E.J.</i> 1960	Germany 1958	Tariffs	.18 per cent
L. H. Janssen	(2)	Italy 1960	Tariffs	max. .1 per cent
H. G. Johnson	<i>Manchester School</i> 1958	U. K. 1970	Tariffs	max. 1.0 per cent
A. Singh	(3)	Montevideo Treaty Countries	Tariffs	max. .0075 per cent

(3) Unpublished calculation made by A. Singh based on data found in A. A. Faraq, *Economic Integration: A Theoretical, Empirical Study*, University of Michigan, Ph.D. Thesis, 1963.

Let us look at some of the findings. In the original Harberger study [14] the benefits for eliminating monopoly in the United States would raise income no more than 1/13 of 1 per cent. Schwartzman's [28] study which recomputes the benefits of eliminating monopoly by comparing Canadian monopolized industries as against counterpart competitive U.S. industries, and vice versa in order to determine the excess price attributable to monopoly, ends up with a similar result. Similarly, the benefits attributed to superior resource allocation as a consequence of the Common Market or a European Free Trade Area are also minute—usually much less than 1 per cent.

The calculations made by Scitovsky of the benefits to the Common Market (based on Verdoorn's data) led him to the conclusion that "... the most striking feature of these estimates is their smallness. The one that is really important (for reasons to appear presently), the gain from increased specialization . . . which is less than one-twentieth of one per cent of the gross social product of the countries involved. This is ridiculously small . . ." [29, p. 64]. J. Wemelsfelder [33, p. 100] has calculated that the welfare gain of reducing import duties and increasing imports and exports accordingly amounts to .18 of 1 per cent of national income. Harry Johnson in an article on England's gain in joining a Free Trade Area [17, pp. 247 ff.] calculates the net gain from trade at less than 1 per cent. That is, Johnson arrives at the conclusion that 1 per cent of the national income would be the absolute maximum gain for Britain from entering the European Free Trade Area.

A recent study by L. H. Janssen [16, p. 132] calculates that the gains from increased specialization for the different countries of the European Economic Community would be largest for Italy, but even here the amount is only $1/10$ of 1 per cent of total production.¹ Janssen points out that, if the production gain for Italy due to specialization were calculated by Scitovsky's method, which he believes involves an overestimation, "the production gain in the most extreme case is still less than .4 per cent." Janssen concludes, as have others, that the welfare effects of a customs union based on the superior allocation of resources are likely to be trivial. He does, however, point to the possibility "that the mere prospect of the frontiers opening would infuse fresh energy into entrepreneurs." He recognizes that certain qualitative factors may be highly important and that the consequences of growth are certainly more significant than those of allocative welfare.

My research assistant, A. Singh, has calculated the gains from trade (following the Scitovsky method) for the Montevideo Treaty Countries² (Argentina, Brazil, Chile, Mexico, Paraguay, Peru, and Uruguay) and found it to be less than $1/150$ of 1 per cent of their combined GNP. Even if we double or triple this result to allow for such factors as the effect of failing to take account of quantitative restrictions in the analysis, the outcome is still trivial.

Harberger's study on Chile [14] which involves the reallocation of both labor and capital yields a relatively large estimate. Harberger intends to obtain as large an estimate as possible of the consequences of reallocating resources by using what I believe to be (and what he admits to be) rather extreme assumptions in order to obtain maximum outer bounds. Despite this he comes up with a number that is between 9 and 15 per cent. However, no actual data are employed. What are used are outer-bound estimates based on personal impressions. I expect that a careful study similar to the Verdoorn-Scitovsky study would probably come up with numbers that would be no larger than 1 or 2 per cent.

The empirical evidence, while far from exhaustive, certainly suggests that the welfare gains that can be achieved by increasing *only*

¹ R. A. Mundell in a review of Janssen's book appears to reach a similar conclusion to the point made in this paper when he speculates that:

... there have appeared in recent years studies purporting to demonstrate that the welfare loss due to monopoly is small, that the welfare importance of efficiency and production is exaggerated, and that gains from trade and the welfare gains from tariff reduction are almost negligible. Unless there is a thorough theoretical re-examination of the validity of the tools on which these studies are founded, and especially of the revitalized concepts of producers' and consumers' surplus, some one [22, p. 622].

² Based on data found in [11].

allocative efficiency are usually exceedingly small, at least in capitalist economies. In all but one of the cases considered all of the gains are likely to be made up in one month's growth. They hardly seem worth worrying about.

Let us see briefly why these gains are usually small. We cannot prove that we would expect them to be small on purely theoretical grounds. If we combine our theory with what we could agree are probably reasonable estimates of some of the basic magnitudes, then it appears likely that in many cases (but certainly not all *possible* cases) the welfare loss of allocative inefficiency is of trivial significance. The idea could be developed with the aid of the diagram employed by Harberger. (See Figure 1.) In Figure 1 we assume that costs are constant

FIGURE 1

within the relevant range. D is the demand function. Under competition price and quantity are determined at the intersection C . The monopoly price is above the competitive price equal to AB in the figure. The monopoly output is determined at the point A . The welfare loss due to monopoly, which is the same as the welfare gain if we shifted to competition, is equal to the triangle ABC . We obtain an approximation to this amount by multiplying the price differential AB by the quantity differential BC by one-half and multiplying this by the proportion of national income in industries involving the misallocation.

Let us play around with some numbers and see the kind of results we get as a consequence of this formulation. Suppose that half of the national output is produced in monopolized industries and that the price differential is 20 per cent and that the average elasticity of demand is 1.5. Now the outcome will turn out to be $1\frac{1}{2}$ per cent. But we really used enormous figures for the misallocation. And yet the result

is small. Monopoly prices, according to estimates, appear to be only about 8 per cent on the average above competitive prices. We can substitute some reason other than monopoly for the misallocation and still come out with similar results.³

Consider the cases of subsidized industries under some sort of governmental inducements to growth; and that of governmentally run industries. In the subsidy case the calculation would be similar. Suppose that as much as 50 per cent of the industries are subsidized to the extent of a 20 per cent difference in cost and that the output point on the demand function is where elasticity is unity. This last point may be reasonable since the operators of subsidized industries might want gross revenue to be as large as possible. If, on the other hand, we assume that they are profit maximizers and restrict output to a greater extent, then we might assume a price elasticity of two. This latter, however, is unlikely because monopoly profits are inconsistent with subsidized industries. Those who receive the subsidy would have the legitimate fear that the subsidy would be lowered if unusual profits were earned. Hence, behavior in the direction of revenue maximization appears reasonable and the calculated welfare loss is less than 2 per cent.

A similar result could be achieved in the case in which the government runs industries that affect 50 per cent of the national income of an economy. In all the cases we have considered, the magnitudes chosen appear to be on the large side and the outcome is on the small side.

Of course, it is possible that the magnitude of allocative inefficiency would be large if there are large discontinuities in productivity between those industries where inputs are located and those industries to which the same inputs could be moved. This, in effect, is the basic assumption that Harberger made in his study of Chile [14]. But if it turns out that there is a reasonable degree of continuity in productivity, and that the only way shifts could be made is by simultaneously increasing either social overhead capital or direct capital in order to make the shifts involved, then, of course, a great deal of the presumed gains would be eaten up by the capital costs and the net marginal gains would turn out to be rather small. My general impression is that this is likely to be the case in a great many underdeveloped countries where

³For the sake of completeness we should take the income effect into account in our estimation of consumer surplus. It may readily be seen that this magnitude is likely to be exceedingly small. Suppose that the initial effect of a superior allocation is 1 per cent; then the income effect for a noninferior good will be to shift the demand function to the right by 1 per cent on the average. Thus, the addition to consumers' surplus will be 1 per cent, and the consumers' surplus foregone will be roughly 1 per cent of 1 per cent. If we consider all consequent effects in a similar vein, then the estimated welfare loss will be .010101 . . . < .0102. The actual magnitude will, of course, be smaller because the demand will shift to the left in the case of inferior goods. For an excellent discussion of these matters see A. P. Lerner [21].

differential productivities appear to exist between the agricultural sector and the industrial sector. One cannot go beyond stating vague impressions since there is a lack of hard statistical evidence on this matter.

Why are the welfare effects of reallocation so small? Allocational inefficiency involves only the net marginal effects. The basic assumption is that every firm *purchases and utilizes* all of its inputs "efficiently." Thus, what is left is simply the consequences of price and quantity distortions. While some specific price distortions might be large it seems unlikely that all relative price distortions are exceptionally large. This implies that most quantity distortions must also be relatively small since for a given aggregate output a significant distortion in one commodity will be counterbalanced by a large number of small distortions in the opposite direction in quantities elsewhere. While it is possible to *assume* relative price distortions and quantity distortions that would be exceedingly high, it would be difficult to believe that, without intent, the sum of such distortions should be high. However, it is not *necessarily* so on purely *a priori* grounds.

There is one important type of distortion that cannot easily be handled by existing microeconomic theory. This has to do with the allocation of managers. It is conceivable that in practice a situation would arise in which managers are exceedingly poor, that is, others are available who do not obtain management posts, and who would be very much superior. Managers determine not only their own productivity but the productivity of all cooperating units in the organization. It is therefore possible that the actual loss due to such a misallocation might be large. But the theory does not allow us to examine this matter because firms are presumed to exist as entities that make optimal input decisions, apart from the decisions of its managers. This is obviously a contradiction and therefore cannot be handled.

II. *X-Efficiency: The Empirical Evidence*

We have seen that the welfare loss due to allocational inefficiency is frequently no more than $1/10$ of 1 per cent. Is it conceivable that the value of *X*-inefficiency would be larger than that? One way of looking at it is to return to the problem of the welfare loss due to monopoly. Suppose that one-third of the industries are in the monopolized sector. Is it possible that the lack of competitive pressure of operating in monopolized industries would lead to cost $3/10$ of a per cent higher than would be the case under competition? This magnitude seems to be very small, and hence it certainly seems to be a possibility. The question essentially, is whether we can visualize managers bestirring themselves sufficiently, if the environment forced them to do so, in order to reduce

costs by more than 3/10 of 1 per cent. Some of the empirical evidence available suggests that not only is this a possibility, but that the magnitudes involved are very much larger. As we shall see, the spotty evidence on this subject does not prove the case but it does seem to be sufficiently persuasive to suggest the possibility that *X*-efficiency exists, and that it frequently is much more significant than allocational efficiency.

Professor Eric Lundberg in his studies of Swedish industries points to the case of the steel plant at Horndal that was left to operate without any new capital investment or *technological change*, and furthermore maintenance and replacement were kept at a minimum, and yet output per man hour rose by 2 per cent per annum. Professor Lundberg asserts that according to his interviews with industrialists and technicians "sub-optimal disequilibrium in regard to technology and utilization of existing capital stock is a profoundly important aspect of the situation at any time." (This according to Gorin Ohlin's summary of Lundberg's findings [24].) If a suboptimal disequilibrium exists at any time, then it would seem reasonable that under the proper motivations managers and workers could bestir themselves to produce closer to optimality, and that under other conditions they may be motivated to move farther away from optimality.

Frederick Harbison reports visiting two petroleum refineries in Egypt less than one-half mile apart. "The labor productivity of one had been nearly double that in the other for many years. But recently, under completely new management, the inefficient refinery was beginning to make quite spectacular improvements in efficiency with the same labor force" [15, p. 373]. We may inquire why the management was changed only recently whereas the difference in labor productivity existed for many years. It is quite possible that had the motivation existed in sufficient strength, this change could have taken place earlier.

In a recent book on the firm, Neil Chamberlain [5, p. 341] visualizes his firms reacting to variances between forecasted revenues and expenditures and actual. He quotes from the president of a corporation: "Actual sales revenue for the fiscal year varied one per cent from the original forecast. Expenditures varied 30 per cent. The reasons were practically entirely due to manufacturing problems of inefficiency and quality. . . . The only actions specifically taken were in attempted changes in methods of production . . . [and] the use of an engineering consulting firm. . . ." One would have thought that the cost-reducing activities mentioned could be carried out irrespective of the variance. Nevertheless, the quotation clearly implies that, in fact, they would not have been motivated to attempt the changes were it not that they were stimulated by the variance.

Before proceeding to present more empirical evidence on the possible magnitude of *X*-efficiency it is of importance to say something about the nature of the data. The empirical evidence does not present any unambiguous cases. Most of the evidence has to do with specific firms or, at best, industries, and not for the economy as a whole. In the evidence presented on allocative efficiency the entire economy was considered. It is quite possible that the cases considered are entirely atypical and could not be duplicated in large segments of the economy. In addition, the cases do not always deal with *X*-efficiency in a pure sense. Some additional inputs or reallocations are sometimes involved. Also uncertainty elements and accidental variations play a role. Nevertheless, it seems that the magnitudes involved are so large that they suggest that the conjecture that *X*-efficiency is frequently more significant than allocative efficiency must be taken seriously.

Now let us turn to Tables 1 and 2. In contrast to Table 1 where the misallocation effects are small, we see in Table 2 that the *X*-efficiency effects, at least for specific firms, are usually large. Table 2 abstracts (in the interest of conserving space) from a much more comprehensive table developed by Kilby [19] that summarizes the results of a number of ILO productivity missions. (I usually picked for each country the first three and the last items contained in Kilby's table.) It is to be observed that the cost-reducing methods used do not involve additional capital nor, as far as one can tell, any increase in depreciation or obsolescence of existing capital. The methods usually involve some simple reorganizations of the production process, e.g., plant-layout reorganization, materials handling, waste controls, work methods, and payments by results. It is of interest that the cost reductions are frequently above 25 per cent and that this result is true for a technically advanced country such as Israel as well as for the developing countries considered in other parts of the table. If the firms and/or operations considered are representative, then it would appear that the contrast in significance between *X*-efficiency and allocative efficiency is indeed startling. Representativeness has not been established. However, the reports of the productivity missions do not suggest that they went out of their way to work only on cases where large savings in costs could be obtained. By comparative standards (with other productivity missions) some of the results were modest, and in some cases Kilby reports that when some members of the missions returned to some of the firms they had worked on previously (e.g., in Pakistan) they found a reversion to previous methods and productivities.

There are of course a number of other studies, in addition to those by Lundberg and Harbison just mentioned which present results similar to the ILO reports. L. Rostas in his study of comparative pro-

ductivity in British and American industry [26] points to the finding that differences in amount and quality of machinery per worker and the rates of utilization and replacement do not account for the entire difference in output per worker in the two countries. He further states

that "... in a number of industries (or firms) where the equipment is very largely identical in the U.S. and U.K., eggs, boots and shoes, tobacco, strip steel (or in firms producing both in the U.K. and U.S. . . .), there are still substantial differences in output per worker in the U.K. and the U.S." Clearly there is more to the determination of output than the obviously observable inputs. The nature of the management, the environment in which it operates, and the incentives employed are significant.

That changes in incentives will change productivity per man (and cost per unit of output) is demonstrated clearly by a wide variety of studies on the effects of introducing payments by results schemes. Davison, Florence, Gray, and Ross [7, p. 203] review the literature in this area for British industry, survey the results for a number of manufacturing operations, and present illustrative examples of their findings from a number of firms. The summary of their findings follows: "The change in output per worker was found to vary among the different operations all the way from an increase of 7.5 per cent to one of 291 per cent, about half the cases falling between 43 per cent and 76 per cent. Such increases in output, most of them large, from our 'first-line' case histories, and from additional evidence, were found not to be just a 'flash in the pan' but were sustained over the whole period of study."

Roughly similar findings were obtained for the consequences of introducing payments by results in Australia, Belgium, India, the Netherlands, and the United States [36]. In Victoria it was found that "soundly designed and properly operated incentive plans have in practice increased production rate in the reporting firms from 20 to 50 per cent." In the Netherlands labor efficiency increases of 36.5 per cent were reported. It seems clear that with the same type of equipment the working tempo varies considerably both between different workers and different departments. Appropriate incentives can obviously change such tempos considerably and reduce costs, without any changes in purchasable inputs per unit.

The now-famous Hawthorne Studies [25] suggest that the mere fact that management shows a special interest in a certain group of workers can increase output. That is, management's greater interest in the group on whom the experiments were tried, both when working conditions were improved and when they were worsened, created a positive motivation among the workers. (The magnitudes were from 13 to 30 per cent [20].) In one of the ILO missions to Pakistan an improvement in labor relations in a textile mill in Lyallpur resulted in a productivity increase of 30 per cent. Nothing else was changed except that labor turnover was reduced by one-fifth [37] [38].

Individual variations in worker proficiency are probably larger than plant differences. Frequently the variation between the best to poorest worker is as much as four to one. Certainly improved worker selection could improve productivity at the plant level. To the extent that people are not working at what they are most proficient at, productivity should rise as a consequence of superior selection methods [13, p. 147].

Although there is a large literature on the importance of psychological factors on productivity, it is usually quite difficult to assess this literature because many psychologists work on the basis of high- and low-productivity groups but do not report the actual numerical differences. In general, it seems that some of the psychological factors studied in terms of small-group theory can account for differences in productivity of from 7 to 18 per cent. The discoveries include such findings as (1) up to a point smaller working units are more productive than larger ones; (2) working units made up of friends are more productive than those made up of nonfriends; (3) units that are generally supervised are more efficient than those that are closely supervised [1]; and (4) units that are given more information about the importance of their work are more proficient than those given less information [32]. A partial reason for these observed differences is probably the likelihood that individual motivation towards work is differently affected under the different circumstances mentioned.

The shorter-hours movement in Western Europe and in the United States, especially up to World War I, has some interesting lessons for productivity differentials without capital changes. Economists frequently assume that for a given capital stock and quality of work force, output will be proportional to number of hours worked. Experiments during World War I and later showed that not only was the proportionality law untrue, but that frequently *absolute* output actually increased with reductions in hours—say from a ten-hour day to an eight-hour day.⁴ It was also found that with longer hours a disproportionate amount of time was lost from increased absenteeism, industrial accidents, and so on. In many cases it would obviously have been to a firm's interest to reduce hours below that of the rest of the industry. Firms could have investigated these relations and taken advantage of the findings. For the most part, governments sponsored the necessary research on the economics of fatigue and unrest under the stimulus of the war effort, when productivity in some sectors of the economy was believed to be crucial. The actual reduction of hours that took place

⁴ The empirical findings and experimental literature are reviewed in a number of places. For a brief review of the literature see [37]. See page 5 for bibliography of major works in the area.

was a consequence of the pressure of labor unions and national legislation.

In this connection it is of interest to note that Carter and Williams [4, pp. 57ff.] in their study of investment in innovations found that a high proportion (over 40 per cent) was of a "passive" character—i.e., either in response to the "direct pressure of competition" or "force of example of firms (etc.) other than immediate rivals." Unfortunately it is difficult to find data that would represent the obverse side of the coin; namely, data that would suggest the degree to which firms do not innovate for lack of a sufficient motivating force, such as a lack of competitive pressure. However, there is a great deal of evidence that the delay time between invention and innovation is often exceedingly long (sometimes more than 50 years),⁵ and the lag time between the use of new methods in the "best practice" firms in an industry and other firms is also often a matter of years. Salter in his study on *Productivity and Technical Change* [27, p. 98] points to the following striking example. "In the United States copper mines, electric locomotives allow a cost saving of 67 per cent yet although first used in the mid-twenties, by 1940 less than a third of locomotives in use were electric."⁶ Other similar examples are mentioned by Salter and others. A survey of industrial research undertaken by 77 companies showed that one-third were carrying on research for "aggressive purposes," but that two-thirds were "forced into research for defensive purposes."

The relation between the "cost" of advice or consulting services and the return obtained has not been worked out for the ILO productivity missions as a whole. In one case (in Pakistan) the savings affected in three textile mills as a consequence of the work of the mission during the year that the mission was there "represented about 20 times the entire cost of the mission in that year." While the study does not indicate how representative this result was, the impression one gets is that rates of return of rather large magnitudes are not entirely unusual.

J. Johnston studied the return to consulting services in Great Britain.

⁵ See the table in [9, pp. 305-6].

⁶ [27]. See especially Appendix to Chapter 7, "Evidence Relating to the Delay in the Utilization of New Techniques." It seems to me that Salter did not quite draw the only possible conclusion from his Table 11. Plants with no significant changes in equipment, method, and plant layout had quite startling changes in output per man-hour, especially if we consider the fact demonstrated in the table that output per man-hour frequently falls under such circumstances. The range of variation in the changes (24 per cent) is larger for the plants without significant changes in equipment, etc., than for those with significant improvements. This is not to argue against the thesis that changes in techniques are important, but to suggest that significant variations in production can and do occur without such changes.

⁷ See [3] for source.

For the class of jobs where it was possible to make a quantitative assessment of the results (600 jobs were involved), it was found that on the average the rate of return was about 200 per cent on consulting fees [18, p. 248]. Johnston's study is of special interest for our purposes because (a) it is a very careful study, and (b) the magnitudes of increases in productivity are of the same order (although the variations are less extreme) as those obtained in underdeveloped countries. The nature of the consulting work was not too dissimilar to that carried out by the ILO teams. On the whole they involved improvements in general management, plant layout, personnel, production procedures, selling organization, management and budgeting and accounting systems. For the consulting jobs whose consequences were quantitatively assessed, the average increase in productivity was 53 per cent, the lowest quartile showed an increase of 30 per cent, and the highest quartile 70 per cent [18, p. 273].

The studies mentioned deal with examples that are more or less of a microeconomic nature. In recent years we have had a number of studies that are their *macroeconomic* complements. The work of Solow, Aukrust, Denison, and others show that only a small proportion of increase in GNP is accounted for by increases in inputs of labor or capital. The "unexplained residual" covers about 50 per cent to 80 per cent of growth in advanced countries [2] [10] [23] [30] [31]. The residual comprehends a greater range of "noninput" growth factors (e.g., technological change, education of the labor force) than was covered in the examples we considered, but the motivational efficiency elements may account for some fraction of the residual. (E.g., Johnston estimates that one quarter of the annual increase in product is accounted for by consulting services.)

What conclusions can we draw from all of this? First, the data suggest that there is a great deal of possible variation in output for similar amounts of capital and labor and for similar techniques, in the broad sense, to the extent that technique is determined by similar types of equipment. However, in most of the studies the nature of the influences involved are mixed, and in some cases not all of them are clear to the analyst. In many instances there appears to have been an attempt to impart knowledge, at least of a managerial variety, which accounts for *some* of the increase in output. But should this knowledge be looked upon as an increase in inputs of production in all instances? Although the first reaction might be that such attempts involve inputs similar to inputs of capital or labor, I will want to argue that in many instances this is not the case.

It is obvious that not every change in technique implies a change in knowledge. The knowledge may have been there already, and a change

in circumstances induced the change in technique. In addition, knowledge may not be used to capacity just as capital or labor may be underutilized. More important, a good deal of our knowledge is vague. A man may have nothing more than a sense of its existence, and yet this may be the critical element. Given a sufficient inducement, he can then search out its nature in detail and get it to a stage where he can use it. People normally operate within the bounds of a great deal of intellectual slack. Unlike underutilized capital, this is an element that is very difficult to observe. As a result, occasions of genuine additions to knowledge become rather difficult to distinguish from those circumstances in which no new knowledge has been added, but in which existing knowledge is being utilized to greater capacity.

Experience in U.S. industry suggests that adversity frequently stimulates cost-reducing attempts, some of which are successful, within the bounds of existing knowledge [12]. In any event, some of the studies suggest that motivational aspects are involved entirely apart from additional knowledge. The difficulty of assessment arises because these elements are frequently so intertwined that it is difficult to separate them.

Let us now consider types of instances in which the motivational aspect appears fairly clearly to play a role. The ILO studies discuss a number of cases in which there had been a reversion to previous less efficient techniques when demonstration projects were revisited after a year or more. This seems to have occurred both in India and in Pakistan [38, p. 157]. Clearly, the new knowledge, if there were such knowledge, was given to the management by the productivity mission at the outset, and the new management methods were installed at least for the period during which the productivity mission was on hand, but there was not a sufficient motivational force for the management to maintain the new methods. The "Hawthorne Effects" are of a more clear-cut nature. Here an intentional reversion to previous methods still led to some increases in output simply because the motivational aspects were more important than the changes in the work methods. The ILO mission reports also mention with regret the fact that techniques applied in one portion of a plant, which led to fairly large increases in productivity, were not taken over by the management and applied to other aspects of the production process, although they could quite easily have done so [38, p. 157]. In a sense we may argue that the knowledge was available to the management, but that somehow it was not motivated to transfer techniques from one portion of a plant to another.

Studies which showed increases in output as a consequence of introducing payment by results clearly involve motivational elements. For

the men subjected to the new payment scheme economic motivations are involved. For the management the situation is less clear. It is possible that in many instances the firms were not aware of the possible advantages of payment by results until they obtained the new knowledge that led to the introduction of the scheme. However, it seems most likely that this scheme is so well known that this is not the case in all, or in many instances. Management quite likely had to be motivated to introduce the scheme by some factors either within the firm or within the industry. In any event, these studies clearly suggest that for some aspects of production, motivational elements are significant.

Both the ILO studies and the Johnston study speak of the need to get the acceptance of top management for the idea of obtaining and implementing consulting advice. In addition, the ILO studies make the point that low productivity is frequently caused by top management's concern with the commercial and financial affairs of the firm rather than with the running of the factory. The latter was frequently treated as a very subordinate task. Whether this last aspect involves a lack of knowledge or a lack of motivation is difficult to determine. However, it seems hard to believe that if some top-management people in some of the firms in a given industry were to become concerned with factory management and achieve desirable results thereby, some of the others would not follow suit. Johnston makes the point that, "without the willing cooperation of management the consultant is unlikely to be called in the first instance or to stay for long if he does come in" [18, p. 237]. The ILO missions make similar remarks.

It is quite clear that consulting services are not only profitable to consultants but also highly profitable to many of the firms that employ them. But it is rather surprising that more of these services are not called for. Part of the answer may be that managements of firms are not motivated to hire consultants if things appear to be going "in any reasonably satisfactory rate." There are, of course, numerous personal resistances to calling for outside advice. If the motivation is strong enough, e.g., the threat of the failure of the firm, then it is likely that such resistances would be overcome. But these are simply different aspects of the motivational elements involved.

III. *The Residual and X-Efficiency: An Interpretation*

The main burden of these findings is that *X*-inefficiency exists, and that improvement in *X*-efficiency is a significant source of increased output. In general, we may specify three elements as significant in determining what we have called *X*-efficiency: (1) intra-plant motiva-

tional efficiency, (2) external motivational efficiency, and (3) nonmarket input efficiency.

The simple fact is that neither individuals nor firms work as hard, nor do they search for information as effectively, as they could. The importance of motivation and its association with degree of effort and search arises because the relation between inputs and outputs is *not* a determinate one. There are four reasons why given inputs cannot be transformed into predetermined outputs: (a) contracts for labor are incomplete, (b) not all factors of production are marketed, (c) the production function is not completely specified or known, and (d) interdependence and uncertainty lead competing firms to cooperate tacitly with each other in some respects, and to imitate each other with respect to technique, to some degree.

The conventional theoretical assumption, although it is rarely stated, is that inputs have a fixed specification and yield a fixed performance. This ignores other likely possibilities. Inputs may have a fixed specification that yields a variable performance, or they may be of a variable specification and yield a variable performance. Some types of complex machinery may have fixed specifications, but their performance may be variable depending on the exact nature of their employment. The most common case is that of labor services of various kinds that have variable specifications and variable performance—although markets sometimes operate as if much of the labor of a given class has a fixed specification. Moreover, it is exceedingly rare for all elements of performance in a labor contract to be spelled out. A good deal is left to custom, authority, and whatever motivational techniques are available to management as well as to individual discretion and judgment.

Similarly, the production function is neither completely specified nor known. There is always an experimental element involved so that something may be known about the current state; say the existing relation between inputs and outputs, but not what will happen given changes in the input ratios. In addition, important inputs are frequently not marketed or, if they are traded, they are not equally accessible (or accessible on equal terms) to all potential buyers. This is especially true of management knowledge. In many areas of the world managers may not be available in well-organized markets. But even when they are available, their capacities may not be known. One of the important capacities of management may be the degree to which managers can obtain factors of production that in fact are not marketed in well-organized markets or on a universalistic basis. In underdeveloped countries the capacity to obtain finance may depend on family connections. Trustworthiness may be similarly determined. Some types of

market information may be available to some individuals but not purchasable in the market. For these and other reasons it seems clear that it is one thing to purchase or hire inputs in a given combination; it is something else to get a predetermined output out of them.

Another possible interpretation of the data presented is in connection with the "residual" in economic growth analysis. The residual manifests itself in three basic ways: (1) through cost reduction in the production of existing commodities without inventions or innovations; (2) the introduction of innovations in processes of production; and (3) the introduction of new commodities or, what is the same thing, quality improvements in consumer goods or inputs. We have ignored the introduction of new commodities, but the other two elements are pertinent here. The data suggest that cost reduction that is essentially a result of improvement in *X*-efficiency is likely to be an important component of the observed residual in economic growth. In addition, there is no doubt that, in some of the cases of reduced cost, new knowledge was conveyed to the firms involved, and this too is part of the residual. It is of special interest that such new knowledge involves knowledge dissemination rather than invention. The detailed studies suggest that the magnitudes are large, and hence a significant part of the residual does not depend on the types of considerations that have been prominent in the literature in recent years, such as those that are *embodied* in capital accumulation or in invention. We have considered the problem in terms of decreasing real costs per unit of output. It is clear that for a given set of resources, if real costs per unit of output are decreased, then total output will grow, and output per unit of input will also rise. Such efforts to reduce cost are part of the contribution of the residual to economic growth.

Both competition and adversity create some pressure for change. Even if knowledge is vague, if the incentive is strong enough there will be an attempt to augment information so that it becomes less vague and possibly useful. Where consulting advice is available it is significant that relatively few firms buy it. Clearly, motivations play a role in determining the degree that consulting advice is sought. The other side of the coin is that, where the motivation is weak, firm managements will permit a considerable degree of slack in their operations and will not seek cost-improving methods. Cyert and March [6, pp. 37, 38, 242] point to cases in which costs per unit are allowed to rise when profits are high. In the previous sections we have cited cases in which there was a reversion to less efficient methods after the consultants left the scene. Thus we have instances where competitive pressures from other firms or adversity lead to efforts toward cost reduc-

tion, and the absence of such pressures tends to cause costs to rise.

Some of the essential points made in the previous paragraphs can be illustrated diagrammatically, if (in the interest of simplicity) we allow for abstraction from some of the realities of the situation. The main ideas to be illustrated are as follows: (1) Some firms operate under conditions of nonminimum costs, and it is possible for an industry to have a nonminimal cost equilibrium. (2) Improvements in *X*-efficiency are part of the process of development, and probably a significant proportion of the "residual." In what follows we assume that there are many firms, and that each firm's output is sufficiently small so as not to affect the output, costs, or prices set by other firms. For simplicity we also assume that for each firm there is an average total unit cost (ATUC) curve that has a significant horizontal segment at its trough, and that the output selected will be on that segment. When we visual-

FIGURE 2

ize a firm's costs reacting to competitive conditions in the industry we imply that the entire ATUC curve moves up or down. Some firms are presumed to react to changes in the unit cost of production of the industry as a whole, i.e., to the weighted average of the unit costs of all the firms, in which each firm's weight is in proportion to its contribution to the output of the industry. Here we posit a one-period lag relation. Each firm's expectations of current industry units costs depends on actual industry unit cost in the previous period. If we choose sufficiently small periods, then this seems to be reasonable relation.

In Figure 2 each curve represents the "reaction cost line" of a firm. The ordinate shows the actual unit cost of any firm determined by that firm's reaction to what it believes or expects to be the unit cost performance of the industry as a whole. The alternate expected unit cost per-

formance of the industry is shown on the abscissa. Thus each point on line C_i^t associates the unit cost for firm i in period t , given the average unit cost in the industry in period $t-1$. The lines are drawn in such a way that they reflect the idea that if the unit cost that is the average for the industry is higher, then the firm's unit cost will also be higher. As average industry unit costs fall, some firms are motivated to reduce their unit costs accordingly. The higher the industry unit cost, the easier it is for any firm to search and successfully *find* means for reducing its own cost. Therefore, for a given incentive toward cost reduction, the firm is likely to find more successful ways of reducing its cost when industry costs are high compared to what they might find when they are low. As a consequence the typical reaction unit cost lines are more steeply sloped where industry unit costs are high compared to when they are low. Indeed, at very low industry unit costs the firm reaction cost lines approach an asymptote. It is not necessary for our analysis to assume that all firms are nonminimizers. Therefore some firms may have reaction cost lines that are horizontal.

The curve C^A is the average of the unit costs of all the firms in question, where the weight for any firm's cost is the proportion of its output to the total industry output. C^A is the average reaction cost line for all the firms. The basic assumption is that a firm's costs will be higher if the average industry costs are expected to be higher, and vice versa. Beyond some point, where expected average industry costs are very low, every reaction cost line will be above the 45° line.

In Figure 3 the line P is a locus of equilibrium prices. Each point on the line associates an equilibrium price with a level of industry unit cost in the previous period, which in turn determines the unit costs level of the various firms in the current period. Thus, given the industry unit cost in period $t-1$, this determines the unit cost level for each firm in period t . Each firm in turn will pick that output that maximizes its profits. The sum of all the outputs determines the industry output, and given the demand function for the product, the industry output determines the price. The price will be an equilibrium price if at that price no additional firms are induced to enter the industry or to withdraw from it. Thus the price for each industry unit cost is determined in accordance with conventional price theory considerations. If the price at the outset is above equilibrium price, then the entry of firms will bring that price down toward equilibrium, and if the price is below equilibrium, marginal firms will be forced to leave the industry, which in turn will cause the price to rise. Thus at every level of industry unit cost in period $t-1$ there is a determinate number of firms, that number consistent with the associated equilibrium price.

The point E in Figure 3, the intersection between curve C^A and the 45° line, is an equilibrium point for all the firms. The process envisioned is that each firm sets its cost in period t in accordance with its expectation of the industry cost, which by assumption is what the industry cost was in period $t-1$. This is a one-period lag relation. Each firm finds out what all of its competitors were doing as a group in terms of cost and reacts accordingly in the next period. If the industry cost is equal to oe then in the subsequent period each firm would set its cost so that the weighted average unit cost of all the firms would be equal to oe . Hence E is an equilibrium point.⁸

But suppose that the initial industry costs were equal to oa . We want to show that this sets up a movement that leads eventually to the point E . The firms' unit costs will average out at ab , which gener-

FIGURE 3

ates a process shown by the set of arrows $abcd$, etc., toward the point E . In a similar fashion, if we start with an industry cost of og , a process is set in motion so that costs move from G toward the point E . Clearly E is a stable equilibrium point. It is to be noted that every point on curve C^A need not presume that the same number of firms exist in the industry. At higher costs more firms exist, but as costs decline, some firms are forced out and fewer firms exist. In terms of the

⁸ In essence the existence of an equilibrium can be shown on the basis of Brouwer's fixed-point theorem. (Point E in Figure 3 can be interpreted as a fixed point.) It would be possible to develop a much more general theory along the same lines based on less restrictive assumptions and achieve essentially the same result. For instance the one-period lag in the reaction unit cost relation can readily be eliminated. Similarly, the unique relation between the firm's unit cost and the industry unit cost level can be relaxed. See G. Debreu [8, pp. 17-18 and p. 26]. However the essence of the theory would remain the same. To conserve space and in the interest of simplicity I present the more restrictive version.

weighted average indicated by the points on the curve C^A , this simply means that some of the outputs will be zero for some of the firms as we get to lower and lower industry costs.

Figure 4 is intended to illustrate the cost reduction aspect of the residual in growth. When we begin the process the average reaction cost line is C_1^A . Firms start at point a and reduce costs along the arrow shown by ab . At this point additional information is introduced into the industry which is reflected in the diagram by the shift in the reaction cost line from C_1^A to C_2^A . Once firms are on C_2^A they then proceed with the cost reduction process as shown by the arrow cd . This illustrates two basic elements involved in the residual, the process of cost reduction in response to the motivation created by competitive pressures, as well as that part of cost reduction that is reflected in actual innovations, and is illustrated by downward shifts in the reaction cost lines.

IV. Conclusions

We have suggested three reasons for X -inefficiency connected with the possibility of variable performance for given units of the inputs.

FIGURE 4

These are: (a) contracts for labor are incomplete, (b) the production function is not completely specified or known, and (c) not all inputs are marketed or, if marketed, are not available on equal terms to all buyers. These facts lead us to suggest an approach to the theory of the firm that does not depend on the assumption of cost-minimization by all firms. The level of unit cost depends in some measure on the degree of X -efficiency, which in turn depends on the degree of competitive pressure, as well as on other motivational factors. The re-

sponses to such pressures, whether in the nature of effort, search, or the utilization of new information, is a significant part of the residual in economic growth.

One idea that emerges from this study is that firms and economies do not operate on an outer-bound production possibility surface consistent with their resources. Rather they actually work on a production surface that is well within that outer bound. This means that for a variety of reasons people and organizations normally work neither as hard nor as effectively as they could. In situations where competitive pressure is light, many people will trade the disutility of greater effort, of search, and the control of other peoples' activities for the utility of feeling less pressure and of better interpersonal relations. But in situations where competitive pressures are high, and hence the costs of such trades are also high, they will exchange less of the disutility of effort for the utility of freedom from pressure, etc. Two general types of movements are possible. One is along a production surface towards greater allocative efficiency and the other is from a lower surface to a higher one that involves greater degrees of *X*-efficiency. The data suggest that in a great many instances the amount to be gained by increasing allocative efficiency is trivial while the amount to be gained by increasing *X*-efficiency is frequently significant.

ON THE SIZE DISTRIBUTION OF FIRMS

By RICHARD E. QUANDT*

The economist's concern with monopoly and industrial concentration and the statistician's interest in stochastic processes have led in recent years to several investigations of the size distribution of firms.¹ The discussion has focused mainly on two problems: (a) the nature of the stochastic processes which might generate the growth of industries, and (b) the statistical matters that arise when we wish to assert that this or that sample can be said to have been drawn from a particular statistical distribution.²

The purpose of this paper is to make a contribution to this subject by using more disaggregated data than has been the case in the past and more refined methods of fitting distributions to the data and judging the goodness of fit. Section I is devoted to some general economic considerations of what one might expect to find as one examines the size distributions of various industries. Section II discusses briefly the sources of data and the distributions that were considered as candidates for explaining the size distribution of firms and considers the merits of judging goodness of fit on the basis of statistical significance. Section III points out the inadequacy of standard procedures for fitting distributions and judging the goodness of fit and introduces the basic notions of a superior method. Section IV finally applies the techniques described in Section III to the various industries and analyzes the results.

I. Aggregation and Economic Considerations

A basic question that has to be answered before an actual sample of observations can be chosen is what the proper level of aggregation is in a study which attempts to explain the size distribution of firms. A particular distribution explains the size distribution of firms only in that it is the limiting outcome of the stochastic process which generates the birth, growth, decline, and death of individual firms.³ Clearly, any such sto-

* The author, professor of economics at Princeton University, is greatly indebted to Stephen M. Goldfeld, John Tukey, and Herbert Simon for many ideas and constructive suggestions. ¹ See [6] [15].

² See [1] [7] [8] [10] [11] [14].

³ One may debate what the proper measure for a firm's size is. It is not the purpose of this paper to add anything to that debate. We measure size in terms of assets in all but two of the samples discussed subsequently. In the case of the two exceptions we use sales as the measure.

chastic process has a set of parameters which characterize it completely; the resulting empirical frequency function of asset sizes must in some sense reflect the parameters of the generating process.

In general one does not know the nature of the stochastic process which generates an industry. Nor is the generating process normally observable directly. We cannot, for example, assume without some solid evidence that firm growth is governed by a Markov process. But in fact this often is assumed, and even as detailed and excellent a study as that of Hart and Prais [6] must content itself in that regard with an analysis of one-period transition matrices⁴ containing the estimated probabilities that a given firm will transit from each size category to each other size category. Empirically observed transition matrices do not, however, imply anything conclusive about the manner in which the observations are generated. The study by Simon and Bonini [15] undertakes a direct test of the Law of Proportionate Effect,⁵ and their sample confirms this hypothesis. The study of Hart and Prais further confirms it [6, p. 170]. But since we can observe the stochastic process which generates an industry only indirectly, an attempt at detailed verification of such hypotheses as those mentioned above either must be based on the assumption that the same stochastic process applies to all firms or it must rest on some reasonable criteria of disaggregation so that a given stochastic process can be thought to apply to all firms in the disaggregated sector.

The study of Simon and Bonini deals, for the most part, with highly aggregative data such as the 500 largest firms in 1955 as published by *Fortune*. Hart and Prais use figures which are equally unselective, in that they choose firms whose shares were quoted on the London Stock Exchange. The use of firms which encompass the entire economy rather than the use of firms restricted to some particular industry is justified by Simon and Bonini on two grounds: (1) that their stochastic growth model makes no reference to any specific features of cost functions—except that costs are constant above some minimum point; and (2) that if firms in each industry are distributed according to the Pareto distribution with slopes close to one, so will firms in the composite industry obtained by amalgamating individual industries [15, pp. 612–13].⁶

Neither of these arguments is fully convincing. The former omits the fact that—whatever specific models may assume—in reality cost functions are likely to be different and conditions of entry and exit are likely to be different, not only among but within industries. The latter

⁴ The period is fairly long in the Hart and Prais study, ranging from 11 to 15 years.

⁵ A random variable is said to obey the Law of Proportionate Effect if it undergoes random proportionate changes from period to period [15, p. 612].

⁶ By slope the authors refer to the α in the formula for the Pareto distribution $F(x) = 1 - (k/x)^\alpha$.

suffers from ambiguity in that it is not clear how individual industries are to be defined in order to yield Pareto distributions with comparable slopes; clearly there always exists *some* definition of industries such that the resulting asset size distributions within each are not Pareto distributions at all. The question then is whether such definitions are more or less reasonable with respect to the homogeneity of firms contained in the specific industries than some alternative definitions might be. We can therefore argue that (1) we have no assurance a priori that various industries will have Pareto distributions with comparable slopes, and (2) any assumption about the comparability on an interindustrial basis of the parameters of the distribution of firms must be based on an explicit model of how industries are generated.

For illustrative purposes consider the simplest of Champernowne's [1] models of income distribution and assume that, *mutatis mutandis*, it is to be applied to the asset distribution of firms. The model assumes that a denumerable set of proportional asset (income) classes is given with transition probabilities governing the movement of assets from class to class. It is assumed (1) that the probability of an asset shifting by k classes depends only on the number k and not on the absolute initial level of assets; (2) that upward shifts involve at most one asset class; and (3) that the expected number of transitions for all assets is negative.⁷ Under these assumptions it can be shown that the limiting distribution of asset (income) sizes is the Pareto distribution exactly. Even if all the assumptions of this attractive model are retained, what guarantee or what reason for belief does one have that the transition matrix in one industry will be the same, or nearly the same, as in another? In general one cannot assume the interindustry stability of transition matrices. If one is willing to hypothesize, contrary to what some have held, that cost and demand functions have something to do with the manner in which industries develop, one may arrive at a model of industry development in which transition matrices depend on the following factors:

1. The nature of the short-run cost function. The more steeply the short-run marginal cost function rises in the neighborhood of the profit-maximizing point, the less likely are significant increases in output; but what is perhaps more important, the greater is the penalty for not achieving the optimum. Thus failure to reach the optimum has a higher probability of causing a downward transition. Of course, if short-run marginal cost curves were typically horizontal, no interindustry differences would arise from this source.

2. The nature of the long-run cost function, the general ease or difficulty of expanding plant and equipment—including such items as the relation between increases in demand which are smooth and increases

⁷ This assumption assures that the process is nondissipative.

in output which, by the nature of the relevant technology, may be achieved only in discrete steps.

3. The nature of oligopolistic arrangements—or the absence thereof—in a given industry.

4. The general configuration of competing products, changes in relative technology, and changes in relative demands. It would indeed be surprising if individual industries behaved substantially similarly, irrespective of wide differences among the underlying forces that generate them. But it is not even plausible to suggest that only the values of certain parameters will be different; in all likelihood the nature of the stochastic process itself will differ from case to case. Accordingly it would be surprising if the same distribution (with different estimated values for the parameters) were to fit all cases.

These considerations clearly suggest the dangers in using aggregated data drawn from several sectors of the economy. These data, having been generated in part by one sort of mechanism and in part by another, cannot be expected to yield reliable results on the whole. In particular, the distribution of firms in a composite industry may be quite different from the distributions of the individual industries which are the sources of the composition.

II. Data and Distributions

Selection of Samples. Since there are no criteria for defining an industry which are free from arbitrariness, it seemed sensible to use definitions commonly used and accepted. With the exception of the two composite samples of the *Fortune* lists of the 500 largest firms in the United States in 1955 and 1960, the samples chosen represent industries according to 4-digit S.I.C. classes. The list of actual industries selected is displayed in Table 1.⁸ The sizes of firms are measured in terms of assets. The 1963 Dun and Bradstreet *Million Dollar Directory* was the source for the firms in each classification. Actual asset figures were procured from the various relevant *Moody's Manuals*.⁹ If a given firm listed in Dun and Bradstreet was not listed in Moody's, it was eliminated from the sample. Similarly we eliminated firms for which assets were not listed in Moody's or which were listed as subsidiaries of some parent firm and for which no separate balance sheet was provided. These restrictions, together with our reliance on the *Million Dollar Directory*, tend to eliminate the small firms. Although it has been argued in the literature that it is basically the right tail of the distribution which is of prime interest, the selection procedure is thus not free of arbitrariness.

⁸ We also display abbreviated code names given to them, which were retained throughout the computations as having higher mnemonic value than S.I.C. numbers.

⁹ *Moody's Industrial Manual*, 1962, 1963; *Moody's Bank and Finance Manual*, 1963; *Moody's Transportation Manual*, 1962. Some of our samples are thus from 1962 and some from 1963.

TABLE 1—LIST OF INDUSTRIES

S.I.C. Number	Name	Code Name
1311	Crude Petroleum and Natural Gas	CRUDPET
6000	Banks (Massachusetts)	MASSBANK
6000	Banks (Illinois)	ILLBANK
6000	Banks (New York)	NYBANK
1511	General Building Contractors	BILDCONT
2011	Meat Packing Plants	MEATPACK
2082	Malt Liquors	MALTICK
2421	Sawmills and Planing Mills	SAWMILL
2621	Paper Mills	PAPERMIL
2731	Books—Publishing and Printing	BOOKS
2818	Industrial Organic Chemicals	CHINDORG
2819	Industrial Inorganic Chemicals	INDINORG
2851	Paints, Varnishes, Lacquers, and Enamels	PAVALAC
2911	Petroleum Refining	PETROREF
3069	Fabricated Rubber Products	FABRUB
3141	Footwear	FOOTWEAR
3312	Blast Furnaces	BLASTFUR
3321	Gray Iron Foundries	GRIFOUND
3441	Fabricated Structural Steel	FABSTEEL
3522	Farm Machinery and Equipment	FRMEQUIP
3571	Computing and Accounting	CACTMACH
3621	Motors and Generators	MOTORGEN
4213	Trucking	TRUCKING
5064	Electrical Appliances, TV, Radio	ELECTAPP
1421	Crushed and Broken Stone	CRUBROST
2033	Canned Fruits, Vegetables, Preserves, etc.,	CANNING
3461	Metal Stamping	METSTAMP
3679	Electronic Components and Accessories	ELECTCOM
4011	Railroads, Line Haul Operating	RAILROAD
6300	Insurance Companies	INSUR

In particular, the selection criteria did not take into account possible relationships between the size of firm and the shape of the long-run marginal cost curve. It is possible, therefore, that some of the data are partially contaminated by the inclusion of firms which are too small. The particular industries chosen were not selected at random; there was at least a casual attempt to obtain a set of industries with differing numbers of firms in them, differing degrees of product homogeneity, and representing different types of production processes. The banking industry contains so many firms that, for computational ease, we consider as three separate industries banks in Massachusetts, Illinois, and New York.

Distributions Fitted. The statistical distributions mentioned perhaps most frequently as "explaining" the size distribution of firms (or of incomes, or of city sizes, or of any number of more or less peculiar socioeconomic quantities) are the Pareto distribution and the lognormal

distribution. Pareto himself advanced three distributions,¹⁰ and the one commonly referred to as the Pareto distribution, more properly called the Pareto distribution of the first kind, is given by

$$(1) \quad F(x) = 1 - \left(\frac{k}{x}\right)^a,$$

where $F(x)$ is the probability of an observation having a value $\leq x$ and where k and a are parameters. We also employed the Pareto distribution of the second kind:

$$(2) \quad F(x) = 1 - \frac{K}{(x + c)^a},$$

and a simplified form of the Pareto distribution of the third kind, known as the Champernowne distribution,¹¹ given by

$$(3) \quad F(x) = 1 - \frac{Ke^{-bx}}{x^a}.$$

Two additional distributions can be derived from equations (1) and (3), respectively, on the basis of the following—admittedly artificial—assumptions: (1) Imagine that we define a set of firms with outputs which are highly substitutable for each other in production as a “primitive” or “noncomposite” industry. We then form a “composite” industry by taking the largest firm in each of a number of noncomposite industries and adjoining them to each other.¹² (2) Each noncomposite industry has an identical number of members. (3) Firms in each noncomposite industry are distributed according to identical distributions (1) or (3). From these assumptions, it follows that firms in the composite industry are distributed approximately as

$$(4) \quad F(x) = e^{-m(k/x)^a},$$

which we shall call the composite distribution, and

$$(5) \quad F(x) = e^{-m(k/x)e^{-bx}},$$

which shall be called the double or iterated exponential distribution. Finally, as mentioned above, we fitted the lognormal distribution where for convenience we chose the two-parameter family given by

$$(6) \quad F(x) = \int_0^x \frac{e^{-1/2[(\log \xi - \mu)/\sigma]^2}}{\xi \sigma \sqrt{2\pi}} d\xi.$$

¹⁰ See [9].

¹¹ See [15].

¹² This assumption may not be a priori as crude as it sounds for the two *Fortune* samples.

All of these distributions are, subject to specific subsidiary assumptions such as those used in deriving (4) and (5), broadly consistent with the Law of Proportionate Effect. In fitting all of these distributions to all our samples, we are in fact making a twofold query: (1) Does at least one of these distributions fit well in each case and is the prevalence of the Law of Proportionate Effect thus upheld? (2) Can we discriminate successfully among various distributions and the fits they produce if several distributions fit reasonably well, as is to be expected?¹³

The Criterion of Statistical Significance. It is important to note that this study concentrates attention on statistical significance. The acceptability of a hypothesis thus is based upon the absence of statistically significant discrepancies between the hypothesis and the data.

This is clearly not the only way to regard the matter. The hypothesis that the generation of industries is explained by the Law of Proportionate Effect or, indeed, the individual hypotheses represented by (1) to (6) are what may be called *extreme hypotheses*,¹⁴ i.e., hypotheses that nobody would wish to accept literally. In analyzing the discrepancy between an extreme hypothesis and the facts it may be more relevant to concentrate on the degree to which the discrepancy is of consequence for, say, economic theory than the extent to which it is statistically significant. The notion of being of consequence is the more relevant one when we are interested in how good overall an approximation is. Thus a discrepancy may be statistically significant but of no consequence. The emphasis of this paper on statistical significance is justified in the following ways: (a) It is difficult to speak of consequential differences—as opposed to statistically significant ones—without specifying a utility function over the possible discrepancies between theory and facts; (b) relatively gross hypotheses such as the Law of Proportionate Effect can be embodied in a number of ways in particular different mathematical formulations among which it is desirable to discriminate; (c) successful statistical discrimination tends to yield reformulated theories of relatively greater sophistication.

III. *The Theory of Fitting Distributions*

In this section we briefly review standard methods of fitting distributions to samples and of judging the goodness of fit and introduce what, so far, promises to be a superior method.

Typically methods of fitting fall into the following categories: (1) The

¹³ Some skewed distributions would not be expected to fit well a priori. An example is the exponential distribution which, it can be shown, has a theoretical value for the Lorenz measure of the inequality of the distribution which is independent of the parameter of the distribution. In fact, the exponential distribution produces abysmally bad fits to our samples.

¹⁴ See [12, pp. 254-56].

method of moments or quantiles, according to which some theoretical sample moments (or quantiles) are set equal to their sample values, and the resulting equations are solved for the parameters of the distribution; (2) the method of maximum likelihood, which assigns to the parameters of the distribution such values as will maximize the likelihood of the sample actually obtained; (3) the method—employable only if some appropriate transform of the cumulative distribution can be expressed as a straight line—which consists of fitting a straight line to the sample cumulative distribution, appropriately transformed;¹⁵ (4) qualitative methods such as inferring something about the class of admissible or inadmissible distributions from the shape—symmetry versus asymmetry—of the Lorenz curve.¹⁶ Discounting the fourth class of methods as being generally too imprecise for purposes of fine discrimination, we have to admit that each of the other three methods may, under appropriate circumstances, have various desirable statistical properties such as providing estimates which are unbiased or consistent or have some other desirable feature.

Once the parameters of the distribution in question have been estimated, we still face the task of judging the goodness of fit. This is typically accomplished by the χ^2 test according to which data are grouped into r classes, the expected frequencies e_i and actual frequencies f_i in each class are obtained, and the statistic

$$G = \sum \frac{(e_i - f_i)^2}{e_i}$$

is calculated which has approximately the χ^2 distribution with $r - k$ degrees of freedom where k is the number of parameters fitted. The test is obviously unsuitable where fine discrimination is required for the following reasons:

1. The test criterion G is sensitive to the particular grouping selected for the observations and in the case of closely similar hypotheses the answer might depend on what grouping was chosen.
2. The test is not as powerful as it might be if its validity rested on the assumption of some specific alternative hypothesis; but it is pre-

¹⁵ H. S. Simon and C. P. Bonini [15] employ this technique.

¹⁶ It can be shown quite easily that the Lorenz curve associated with the Pareto distribution of the first kind, defined only for values of $a > 1$, is asymmetric. These methods are imprecise, at best, since this property is shared by many other distributions. If, however, the Lorenz curve were symmetric, we may be fairly sure that the sample does not fit the Pareto distribution well. An equally dubious qualitative method is to take sequentially increasing samples and examine the resulting sequence of sample first, second, etc., moments. If these sample moments show a tendency *not* to settle down, but to increase indefinitely with increasing sample size, we may be on fairly good ground to suggest that we are dealing with a sample from a distribution with infinite moments. Unfortunately this method does not tell us which of the many such distributions we may be dealing with.

cisely this kind of situation that is encountered when we wish to choose between, say, the Pareto and the lognormal distributions.

3. The test cannot be validly applied if expected frequencies are very small;¹⁷ this, however, is precisely the case when we are interested in distributions with very long right tails.

4. The value of G may be small, indicating a good fit, but the fitted cumulative distribution and the sample cumulative distribution may still show very significant, systematic divergences from each other.

Points 2 and 4 can be equally well used as a critique of the Kolmogorov-Smirnov test, together with the added problem that critical values of the Kolmogorov-Smirnov statistic are not known in the case in which the parameters of the distribution have actually been estimated from a sample.¹⁸

Because of the variability in the properties of the estimates by the various methods mentioned earlier and because of the great difficulty of achieving subtle discrimination among alternative hypotheses, a new, unified method of estimating and of testing goodness of fit has been developed.¹⁹

This method considers the values of the cumulative distribution at the n sample points x_i , denoted by $F(x_i)$. We assume that the x_i 's are order statistics; that is, that the sample has been so reordered that $x_i \leq x_j$ if $i < j$. By convention $F(x_0) = 0$ and $F(x_{n+1}) = 1$. We form:

$$S = \sum_{i=1}^{n+1} \left(F(x_i) - F(x_{i-1}) - \frac{1}{n+1} \right)^2$$

and choose as our estimates of the parameters of the distribution those values which minimize S .²⁰ The resulting estimates can be shown to be consistent.²¹ It is to be noted that in general this method works for all distributions and is nonparametric in that the properties of the estimates do not depend upon the particular distribution in question.²²

Goodness of fit is tested in two basic ways and a fit is pronounced bad if it fails by either test. The two criteria are the *closeness* of the fit as measured by the value of S at the minimum (the smaller is S , the better is the fit) and by the *randomness* of the fit which is measured

¹⁷ There has been some debate as to what constitutes "small" expected frequencies. See [2].

¹⁸ See, for example [1].

¹⁹ See [10] and [11].

²⁰ Clearly this involves possibly tricky numerical minimization problems. For an effective solution of these problems which was not yet available when these computations were performed, see [4].

²¹ See [10].

²² The reason being that the quantities $F(x_i) - F(x_{i-1})$, called the coverages associated with the order statistics, have identical joint uniform distribution, irrespective of the form of the distribution of x .

by the randomness of the successive residuals $F(x_i) - F(x_{i-1}) - 1/(n+1)$, $F(x_{i+1}) - F(x_i) - 1/(n+1)$, etc. The rationale for testing the residuals for randomness is simple: under the null hypothesis, that is if the data really were generated by the distribution fitted, we would expect some residuals to be positive, some negative, in no predictable order. A systematic deviation from randomness, even with a small S , therefore indicates a bad fit. Randomness itself can be tested in several ways which will be discussed when we turn to an analysis of the data in the next section.

IV. Results of Fitting

It has been shown elsewhere that the standard methods are generally not capable of fine discrimination.²³ In this section we discuss only the results of our new method. Table 2 displays the estimated values of S . The first column gives the number of observations for each sample. Asterisks indicate that the value of S is so high that on the .05 level of significance we must reject the possibility of a good fit.²⁴

Before we can interpret Table 2 we must note the anomaly that in a few instances the Pareto distribution of the first kind fits better than that of the second kind or that the composite distribution fits better than the double exponential. This may appear as paradoxical since these pairs of distributions are essentially of the same form, with one of them having one additional parameter to be fitted. The one with more parameters to be fitted should yield the better fit.²⁵ The answer is that the minimization of S was carried out by numerical methods; hence we cannot be sure that in each case we have reached a global minimum. In fact, during the computations there was occasional evidence of multiple minima—or at least of very flat plateau-type minima—in several instances. In these instances direct search of the parameter space was undertaken until a “reasonable” value of S seemed to have been produced.²⁶

²³ See [11].

²⁴ Critical values for S were derived from sampling experiments in which the distribution was fitted when the null hypothesis was known to be true. See [10]. Linear interpolation was used for adapting the calculated critical values to the present values of N .

²⁵ Note also that these considerations affect the validity of using significance levels of, say, S , derived by fitting only two parameters for testing closeness of fit in a three-parameter case. It is quite likely, however, that when the number of observations is large, this will cause a negligible distortion.

²⁶ Clearly the procedure does not guarantee that a global minimum had been reached. This may cast some doubt on the statements of statistical significance made in the rest of the paper. On the whole, however, we may be confident that the results are reasonably accurate because (a) when direct search of the parameter space was undertaken, it was a fairly thorough search, consisting of picking a new starting point and performing a new set of iterations leading to a—hopefully—smaller minimum; (b) after an “acceptable” value of S was produced, the

Table 2 provides us with the following conclusions:

1. The *S*-values tend to discriminate among the various distributions fairly well. Considering each sample to be a judge who ranks the six candidate distributions, we find Kendall's coefficient of concordance $W = .303$, which is significant on the .001 level. In particular, out of the 32 samples the Pareto distribution of the first kind is rejected in 20 cases, the Pareto distribution of the second kind in 15 cases, and the Champernowne distribution in 11 cases. The other three seem to do much better, being rejected not more than seven times. As potential candidates for general description we thus have only the composite,

search was continued until several new tries failed to produce a smaller minimum; (c) the search was continued until the results showed that the "acceptable minimum" could be achieved from various starting points.

iterated exponential and lognormal distributions left, and we can safely reject the hypothesis that all candidate distributions fit equally well.

2. One of the samples, the Footwear Industry, is not fitted well by any distribution.

3. The Pareto distributions of the first and second kinds and the Champernowne distribution do well for the two *Fortune* samples, for which the composite and iterated exponential distributions—the derivations of which were inspired by the conjectured construction of those samples—do rather badly. The assumptions underlying those derivations seem not to correspond to reality in those cases.

4. In spite of conclusion 1, it is interesting to note that each of the six distributions produces a “best fit” for at least one sample.

5. On a fairly casual basis one might argue that the *S* values for the last five distributions indicate discrepancies between hypothesis and facts which are of not great consequence; the same cannot be argued easily for the Pareto distribution of the first kind which exhibits much larger *S* values on the whole.

In the aggregative Table 3 the letter *S* signifies that the particular sample distribution pair failed the test of closeness at the .05 level of significance.

Three methods have been employed to test the randomness of the residuals. Clearly the results of the three are not independent of each other, but their relative sensitivities differ, and so all three were employed. We further note that nothing is known at present about the power of these tests. Therefore, since most instances in which the null hypothesis is false will tend to induce some nonrandomness of residuals, we cannot analyze questions about the probability that the hypothesis will be rejected when it is false. These methods can be described briefly as follows:

1. Runs of negative and positive residuals were counted and the standard-runs test was performed on each set of residuals at the .05 level of significance.²⁷ The letter *R* in Table 3 indicates that the particular sample-distribution pair failed the runs test of randomness.

2. Orthogonal polynomials of 15th degree were fitted to the various series of residuals.²⁸ If the residuals contain low-frequency oscillations only, the fit will be good, and the percentage reduction in the total sum of squares of residuals owing to fitting the polynomial will be large. If the series of residuals contain only very-high-frequency oscillations, the reduction in the sum of squares will tend to be small. For random series the percentage reduction in the sum of squares will be of intermediate size. The letter *O* in Table 3 indicates that, on the .05 level of signifi-

cance, the percentage reduction in the sum of squares deviated from randomness.²⁹

3. The power spectrum of each series of residuals was calculated and examined by comparison with the power spectrum of series of comparable length generated when the null hypothesis was in fact true³⁰—for significant deviations from the characteristics of the spectrum of white noise—which is indeed the appearance of all the spectra generated under the null hypothesis. The letter *P* is entered in Table 3 where significant amount of power was found at the low frequencies. It should

²⁹ Critical values for the percentage reduction were established by extensive sampling experiments in which the null hypothesis was in fact true. In all but five cases rejection in the above table occurred because of low-frequency oscillations. See [10].

³⁰ See [10].

be noted that the spectral representation is not very meaningful or informative for short series, say for series of length much less than 50. For illustrative purposes we show the spectra for the sample *Fortune* 6 in Figure 1. The first three of these spectra are indistinguishable from those of series of comparable length for which the null hypothesis is true. The last three exhibit noticeable peaks at the low frequencies, indicating nonrandomness.

Some basic conclusions that can now be drawn from Table 3 are as follows:

1. We disqualify a distribution as providing a good fit if it fails by either the criterion of closeness or the criterion of randomness. We shall base our conclusions concerning randomness on the test using orthogonal polynomials. On this basis we obtain the following ranking: (a) the composite distribution (23 good fits), (b) the iterated exponential and lognormal distributions (20 good fits), (c) the Champernowne distribution (17 good fits), (d) the Pareto distribution of the second kind (11 good fits), (e) the Pareto distribution of the first kind (6 good fits). The ordering of the composite and iterated exponential distributions is paradoxical and is probably explained by the computational artifact mentioned earlier. The Champernowne and the Pareto distribution of the second kind have the same number of parameters, hence the former is clearly better; the Pareto distribution of the first kind has one fewer parameter and one might attempt to explain its bad performance in terms of that fact. This would not be satisfactory, however, since both the lognormal and the composite distributions have the same number of parameters as the Pareto distribution of the first kind and yet perform markedly better.

2. Although there is considerable difference in the number of instances in which the various tests of randomness "catch" bad fits, the runs test catching 34 cases, the spectral test 50, and the orthogonal polynomial test 78, there is a very marked overlap in the cases they do catch. One way of verifying this is as follows: Consider a particular pair of tests, say those denoted by the letters R and P . Let the number of occurrences of these letters in Table 3 be N_R and N_P , i.e., $N_R = 34$, $N_P = 50$. On the null hypothesis that the N_R R 's and N_P P 's are distributed randomly in Table 3, the probability of k or more matches in Table 3 (instances in which R and P occur together) is

$$P(k) = \sum_{j=k}^{N_R} \frac{\binom{N_P}{j} \binom{192 - N_P}{N_R - j}}{\binom{192}{34}} .$$

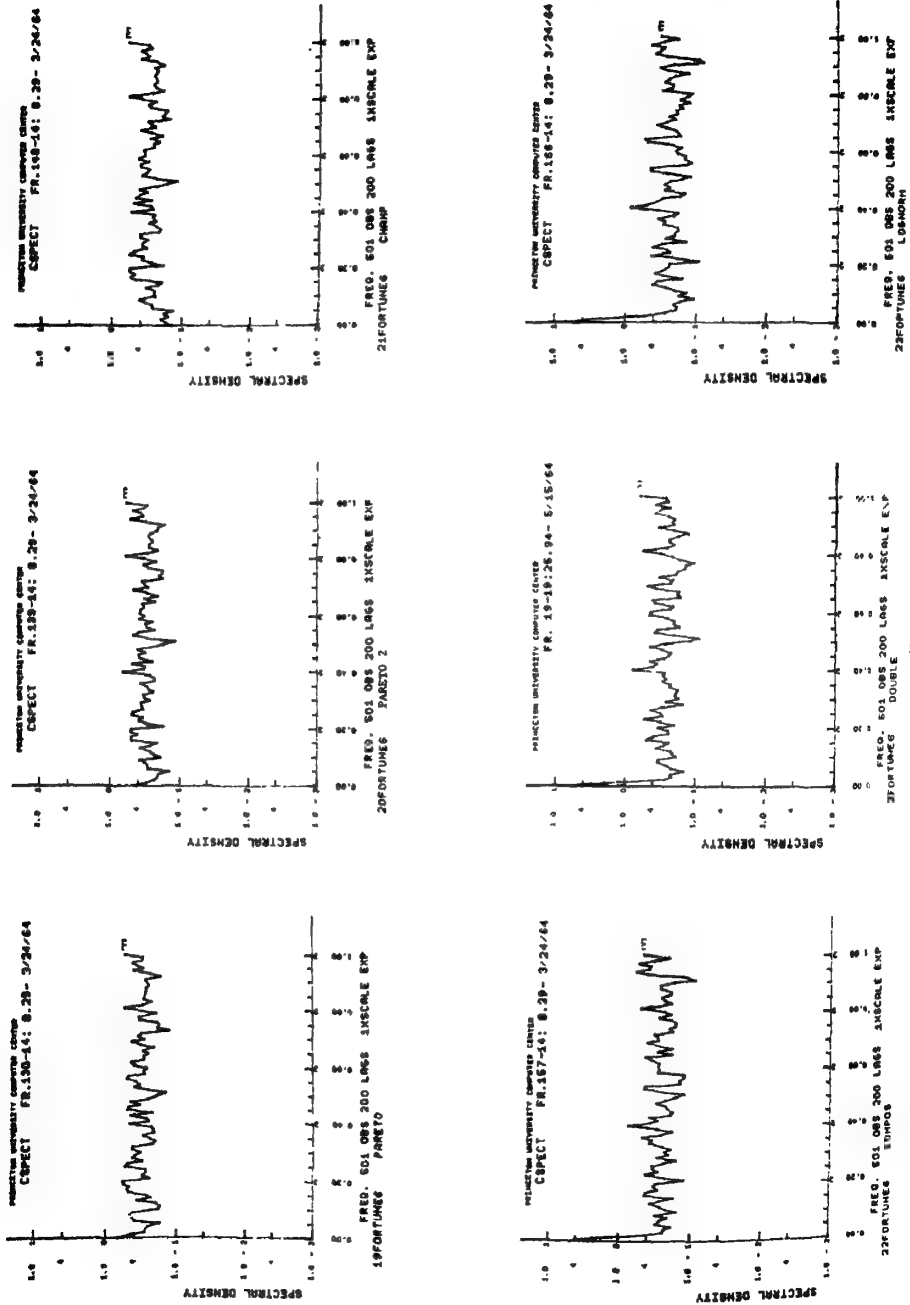

FIGURE 1

For all three possible comparisons this probability is less than 10^{-6} , and we emphatically reject the hypothesis that these tests of randomness catch cases at random.

3. There are four cases where none of the distributions fits well enough. In addition, the Pareto distribution of the first kind does not fit the sample *Fortune* 5 well on the grounds of nonrandom residuals.²¹

4. Discrimination is far from perfect. Basing our judgment of a good fit on the nonappearance of the symbols *S* and *O* in Table 3, we find 15 samples which are fitted well by four or more distributions. However, all of these are samples where the number of observations is less than 60. Discrimination becomes much greater when the number of observations is large. In fact, the number of times the symbols *S*, *R*, *O*, *P* occur in Table 3 is 224. One hundred ten of these occurrences are in the nine samples with more than one hundred observations. The unhappy conclusion from this is that we may not be able to test hypotheses involving subtle discrimination or we may not be able to test even grosser hypotheses—such as the Law of Proportionate Effect—without much larger samples than are typically available. The fact that good fits are fewer when the samples are large suggests that if we had large samples for all our industries, we would generally find many fewer good fits than is the case.

5. The composite distribution and the iterated exponential distribution, the derivation of which was inspired by the hypothetical construction of the *Fortune* samples, do not fit those samples well at all.

V. Concluding Remarks

Fitting distributions and testing the goodness of fit in the manner outlined in Sections II and III lead to fairly good discrimination in many cases among closely similar alternatives. In particular the Pareto distribution of the first kind generally was seen to provide very bad fits. This result contradicts in two ways the view that (a) firm sizes have the Pareto distribution, and (b) that the distributions are not very sensitive to the methods by which the samples are obtained [8, p. 425].

Although the analysis does not suggest that discrepancies between the predictions of the (unadorned) Law of Proportionate Effect are of great consequence, there is statistical evidence that we can discriminate between alternative guises in which the Law may appear. In all likelihood the Law of Proportionate Effect operates together with such complicated conditions on birth and death as to be incapable of yielding a pure test of the law itself. Finally, it is very likely that in

²¹ This sample had been found to agree well with the Pareto distribution earlier. See [15].

many instances we shall be unable to test hypotheses about the distribution of the data, and thus about the mechanism generating them, because of the smallness of the number of observations. In these instances an unavoidable agnosticism may prevail.

DYNAMIC INCOME ADJUSTMENT TO MONEY-SUPPLY CHANGES

By DONALD P. TUCKER*

Recent empirical studies have provided evidence that aggregate investment spending responds to changes in the level of interest rates, but that it responds only gradually, with a considerable distributed lag. Some writers have drawn from this the conclusion that monetary policy, to the extent that its effectiveness comes from its power to influence investment through interest rate changes, works very slowly and cannot be used for cyclical stabilization. This conclusion is not justified, for long distributed lags in investment response can exist without causing comparable lags in the response of aggregate demand to changes in the money supply. The lags and parameter values in other sectors of the economy have fully as much influence as those in investment in determining the dynamics of the system. In particular, lags in the money-demand function tend to counteract, rather than reinforce, the investment lags. In this paper, a dynamic Keynesian income model characterized by distributed lags in the behavioral equations is analyzed to demonstrate this point.

One of the crucial questions for monetary policy is the question of speed of adjustment, of how rapidly production and income respond to changes in the money supply. At issue is whether attempts at counter-cyclical management of the money supply are stabilizing or destabilizing, for monetary policy may, in fact, aggravate business cycles if its effects are mostly felt many months after money-supply changes occur. One of the economic mechanisms through which a change in the money supply is thought to influence real national income operates through the interest rate. Investors base their spending decisions in part, according to this Keynesian argument, on the current and expected future levels of interest rates. When these change in response to a money-supply change, then investment also changes, inducing a corresponding change in consumption spending. Clearly, then, one factor of major importance to the question of the speed of monetary policy is the speed with which investment spending responds to interest rate changes.

In recent econometric studies of investment the most satisfactory results have often been obtained with models in which investment re-

* The author, assistant professor of economics at the University of Chicago, is indebted to the members of the Workshop in Econometrics and Mathematical Economics at the University of Chicago for their suggestions on an earlier draft of this paper.

sponds with a distributed lag to changes in the variables on which depends. Because of its simplicity, the form

$$I_t = a + b_1X_{1,t} + b_2X_{2,t} + \cdots + cI_{t-1}$$

(where X_i is the i th independent variable and t is a time subscript) commonly employed. This form, as is well known, is implied by an investment function in which current investment depends on all current and past values of the independent variables with geometrical declining coefficients. The coefficient of some variable t periods ago is proportional to c^t , where $0 \leq c < 1$. Thus, the lag coefficient, c , is an indicator of the speed of adjustment. If c is close to zero, investment depends hardly at all on the values of variables more than a couple of periods back, and adjustment is rapid. A large c means slower adjustment.

Several investment studies utilizing such a lag model have found both a significant coefficient for some interest rate variable and a moderately large lag coefficient [3] [5] [7, Ch. 7], thus indicating that investment responds directly to monetary stimuli, but only with a distributed lag. It is an easy and intuitively appealing application of the Keynesian framework to judge from such evidence that monetary policy works slowly on the economy, and conclusions of this sort have occasionally appeared in the literature [1, Ch. 12] [2] [3] [6]. The deduction required to reach this conclusion is not a valid one, however. The existence of lags in investment response is not a sufficient condition for monetary policy to work slowly, and it is the burden of this paper to establish this point.

The missing link in the argument is the behavior of the interest rate. The impact of a monetary policy change is transmitted to investment indirectly by inducing changes in the interest rate, and it is clear that the dynamic response of investment spending to a money-supply change cannot be determined without knowledge of how the interest rate responds. If it adjusts only gradually, then this means another lag to be added to the distributed lag in the investment function. However, not only is a vigorous initial interest rate response to be expected, as we shall see, but, in fact, we can not rule out the possibility of interest rate fluctuations sharp enough to shove investment spending immediately to or beyond its new equilibrium level, without any lag at all.

What, then, is the implication for monetary policy of the investment lags so far observed, and how can we find the interest rate behavior they imply? The answers require a framework that is explicitly dynamic, and an obvious approach is to remold the static Keynesian model into a dynamic one by incorporating into it behavioral equations containing

distributed lags. The model, using linear equations for mathematical simplicity, is the following:

- 1) $I_t^* = (1 - j)(a_1 + b_1 Y_t + dr_t) + jI_{t-1}^*$
- 2) $C_t^* = (1 - j)(a_2 + b_2 Y_t) + jC_{t-1}^*$
- 3) $Y_t = C_t^* + I_t^*$
- 4) $M_t^* = (1 - m)(e + fY_t + gr_t) + mM_{t-1}^*$
- 5) $M_t = M_t^*$

where

C^* = desired consumption;

I^* = desired investment;

M^* = desired money holdings;

M = money supply;

Y = income;

r = interest rate;

t = time subscript;

j and m are lag parameters, with $0 \leq j, m < 1$; and

all other symbols are constants.

Equations (1)–(3) specify product demand and the condition that the product market is cleared in every period. Equations (4) and (5) specify the demand for money and the condition that the money market is cleared in every period.

Price and wage changes are ignored. No labor market is considered, and income can change freely without encountering a labor-supply constraint. Thus, the model deals with the impact of monetary policy on real income and employment rather than its impact on the price level.

The money supply is a policy parameter, and it is the only exogenous variable of the system. The model is assumed to have a stable static equilibrium position,¹ the properties of which are obtained by setting each variable equal to its own lagged value. Notice that the lag parameters disappear when this is done; the other constants thus specify the relationships between steady-state values of the variables. Varying j and m thereby permits us to vary the lags in the system without affecting its static properties.

This model represents a dynamic generalization of only one aspect of a Keynesian model. No dynamic process has been formulated to de-

¹ This stability assumption imposes a condition on $(b_1 + b_2)$. See equation (13) and the remarks immediately preceding it.

scribe the response of markets to excess supply and demand. Instead the static equilibrium conditions that the money and product markets be cleared have been converted into the dynamic assumptions that these markets are cleared in every period, and the results of the model are very dependent on these assumptions. For this reason, and for many others, the model is far too simple to be regarded as a serious representation of the real world. Rather, it is simply an illustration, an expository device to help bring out in the conciseness of mathematics the properties of one particular economic adjustment mechanism. The general applicability of the economic principle involved will, I think, become apparent.

I. *Income Response*

A difference equation specifying directly the relationship between Y and M is obtained by combining equations (1)–(5) and eliminating C^* , I^* , M^* , and r by substitution. For our purposes, the essential characteristics of the resulting relationship are given by

$$(6) \quad Y_t - AY_{t-1} = B + D(M_t - mM_{t-1}),$$

where

$$(7) \quad A = \frac{j}{1 - (1 - j) \left(b_1 + b_2 - \frac{df}{g} \right)},$$

$$(8) \quad D = \frac{Ad(1 - j)}{gj(1 - m)},$$

and B is a constant of no importance.

In order to obtain an explicit solution for Y from equation (6) we must specify an initial value for Y and the complete time path of M . Yet, the answer will have no general relevance if we determine the behavior of Y only for the obvious but special case in which Y is at static equilibrium before we change the money supply and is permitted to settle down completely to a new static equilibrium after we change the money supply once. In general, we expect the money supply to change frequently as the monetary authorities react to changing economic conditions, and we would like a result that is still valid if the money supply changes again before the dynamic response to the first change has worked itself out. The question we are asking is this. What portion of the dynamic changes in Y going on continuously can be attributed to any one particular money-supply change that we choose arbitrarily? In other words, suppose we superimpose a permanent change in the money supply, occurring all at once, on top of the time path of M

(fixed or fluctuating) that would otherwise prevail. How will Y now deviate from the time path it would otherwise have followed?

Conceptually, then, we divide M and Y each into two parts. One part of M is the time path the money supply would have followed if the single monetary change whose effect we are analyzing had not taken place. The other part of M represents this change. Likewise, one part of Y is the time path income would have followed if the monetary change we are considering had not occurred, and the other part represents the deviation from this path caused by the monetary change. It is the dynamic pattern of this deviation in Y that we wish to find.

Let $Y_t = Y_t' + Y_t''$ and $M_t = M_t' + M_t''$ for all t . These are substituted into equation (6). Let Y' and M' be the unspecified underlying values to which we are adding a change. The relationship between Y' and M' clearly must be specified by an equation identical to (6) containing only single-primed variables.

This leaves

$$(9) \quad Y_t'' - AY_{t-1}'' = D(M_t'' - mM_{t-1}'').$$

Furthermore, the point of dividing our variables into two parts was in order that we might specify, without loss of generality, that

$$(10) \quad M_t'' = \begin{cases} 0, & t \leq 0 \\ \Delta M, & t = 1, 2, \dots \end{cases}$$

$$Y_t'' = 0, \quad t \leq 0.$$

The condition on Y'' specifies that output cannot be affected by a change in M before that change has occurred.

In analyzing the dynamic properties of this model, we are concerned more with the shape of the path along which equilibrium is approached than with the absolute magnitude of each adjustment. Therefore, it is simpler to express the values of Y'' as ratios to their final equilibrium value (Y_∞''). Define $y_t = Y_t''/Y_\infty''$, and substitute

$$(11) \quad Y_t'' = Y_\infty'' y_t = \frac{D(1-m)}{(1-A)} y_t \Delta M$$

into (9), where the expression for Y_∞'' has been obtained from (9) and (10) by setting $Y_{t-1}'' = Y_t'' = Y_\infty''$.² Given the conditions (10), we can now solve the resulting difference equation sequentially for y_1, y_2, y_3 , etc., and it is readily seen by induction from these results that

² We assume $A \neq 1$. See the following paragraph.

$$(12) \quad y_t = 1 + \frac{m - A}{1 - m} A^{t-1} \quad \text{for} \quad t = 1, 2, \dots,$$

a remarkably simple solution with some very interesting properties.

The magnitude of A , defined by equation (7), clearly determines whether the model is convergent. We know that $0 \leq j < 1$, that $d, g \leq 0$, and that $b_1, b_2, f \geq 0$. Therefore, if $(b_1 + b_2)$ lies within the appropriate range, a range extending from zero somewhat beyond one, then $0 \leq A \leq 1$, and y_t converges monotonically to one. Specifically, the stability condition is

$$(13) \quad b_1 + b_2 < 1 + \frac{df}{g}.$$

The lag parameter of the demand for money, m , appears directly in the solution (12), but j , the investment and consumption lag parameter, does not appear. However, its place is taken by A . When the stability condition (13) is satisfied, then A is a monotonically increasing function of j . In addition, $j=0$ implies $A=0$, and $j=1$ implies $A=1$. Thus, we may treat A as a proxy for the investment and consumption lag parameter.

First of all, note from equation (12) that $m=A$ implies $y_t=1$ for all t . Income adjusts instantly to its new equilibrium value when $m=A$, despite the lags in the demand functions. One lag has canceled the other.

The more general pattern becomes apparent when we examine the first-period response,

$$(14) \quad y_1 = 1 + \frac{m - A}{1 - m} = \frac{1 - A}{1 - m}.$$

For $m < A$, we have $y_1 < 1$; income only adjusts partially at first and must complete its adjustment gradually over the next several periods. As m increases or as A decreases, the first-period response becomes larger, eventually reaching 1.0 when $m=A$. If $m > A$, then income overshoots its equilibrium in the first period and must adjust back in the opposite direction. In either case, y approaches equilibrium asymptotically in succeeding periods, the speed of convergence being determined by the magnitude of A . See Figures 1 and 2 for illustrations of the response of y for different parameter values.

In all cases, investment is the volatile component of income and consumption the stable one. Consumption depends only on income, with a distributed lag, and, for this reason, it inevitably must adjust more gradually than income. This leaves investment as the component that

responds more vigorously to money-supply changes, just as we expect, and the reason is because of its dependence on the interest rate. The underlying forces will become more apparent in the next two sections.

It is clear from equation (12) that the speed with which income converges to its equilibrium is closely related to A . We expect a smaller A to mean more rapid adjustment. However, the relationship is not so simple. In the first place, $m=A$ gives instantaneous adjustment for any A . If $m \neq A$, then y only approaches 1.0 asymptotically, and

FIGURE 1. TIME PATH OF INCOME ADJUSTMENT FOR DIFFERENT MONEY-DEMAND LAGS
(Ratio of accumulated change to total equilibrium change, with $A=0.7$)

adjustment is never entirely complete. In order to enable ourselves to talk of the speed of adjustment, we may arbitrarily say that adjustment is "complete" when the asymptotic approach of y has brought it into the range $0.95 < y < 1.05$ (or some other such narrow band around one). In Figures 1 and 2, the dotted lines mark the boundaries of this range.

In Figure 1, A has been held constant, and yet the speed of adjustment clearly varies with m . When $m < A$, adjustment becomes more rapid as m approaches A . Then it begins to take longer again as m exceeds A . The explanation is that A governs the speed of approach to equilibrium only after the first period. The farther income is from

equilibrium at the end of one period, for given A , the longer it is going to take the series of geometric terms to reach the range between the dotted lines. Yet, equation (14) shows that the distance of y_1 from equilibrium depends on the difference $(m-A)$. In a general sense, then, it is the *difference* between product-demand lags and money-demand lags, as much as it is the inherent character of the lags themselves,

FIGURE 2. TIME PATH OF INCOME ADJUSTMENT FOR DIFFERENT PRODUCT-DEMAND LAGS
(Ratio of accumulated change to total equilibrium change, with $m=0.7$)

that determines the speed of income adjustment. If the difference is small, then adjustment is rapid.

II. Interest Rate Response

The preceding section presents the mathematical solution, but it offers no explanation in economic terms for this surprising result. The key lies in the behavior of the interest rate, so it is necessary first to find the solution for r in this model.

Equations (1), (2), and (3) are combined to give an equation connecting r and Y . As in the preceding section, we divide the variables

into two parts, and this produces an expression in r'' and Y'' from which the constant terms have disappeared. When this is converted into an equation in y , using equations (11) and (8), we obtain

$$(15) \quad r_t'' = \frac{A}{gE(1-A)} (y_t - Ey_{t-1}) \Delta M$$

where

$$(16) \quad E = \frac{j}{1 - (1-j)(b_1 + b_2)}$$

and where A is given by equation (7). The solution (12) for y , together with the condition that $y_0 = 0$, are used in (15) to obtain directly the solution

$$(17a) \quad r_1'' = \frac{A}{gE(1-m)} \Delta M$$

$$(17b) \quad r_t'' = \frac{A}{gE(1-A)} \left[(1-E) - \frac{(m-A)(E-A)}{(1-m)} A^{t-2} \right] \Delta M$$

for $t = 2, 3, \dots$

Comparison of equations (7) and (16) by eye shows that $E > A$ for all relevant parameter values.³ Therefore,

$$\frac{r_\infty}{r_1} = \frac{(1-m)(1-E)}{(1-A)} < (1-m)$$

(the double prime is dropped for simplicity), and this expression may even be zero or negative because $E \geq 1$ according as $(b_1 + b_2) \geq 1$.⁴ In other words, the initial response of the interest rate is to overshoot its new equilibrium (r_∞) if $(b_1 + b_2) < 1$, and, if m is moderately close to one, it takes a big jump far beyond equilibrium. When $(b_1 + b_2) > 1$, on the other hand, it moves away from equilibrium at first. Equations (17) show that the direction of movement of r_1 is the same in either case; it is the sign of r_∞ that is different.

In the second period, the interest rate reverses direction, moving back toward (or beyond) equilibrium. We find

$$\frac{r_2}{r_1} = (1-m) - (E-A) < (1-m),$$

³ $E = A$ if j , d , or f is zero. We may ignore these extreme cases as uninteresting.

⁴ The possibility that r_∞ may be zero is the reason the solution (17) is not expressed as a ratio to r_∞ as was the solution (12) for y .

and this expression may also be negative. A negative value implies that r moves back farther than its initial starting position. Note that r_2 and r_∞ both bear roughly the same relation to r_1 . Regardless of how wildly the interest rate jumps in the first period, its readjustment in the second period returns it to the vicinity of equilibrium.

After its second-period reaction, the interest rate approaches equilibrium asymptotically, and its rate of convergence also depends on the magnitude of A . Note that the sign of $(m-A)$ determines the sign of the second term in equation (17b); the sign of every other factor in that term is independent of the parameter values. It is this term that governs the asymptotic approach to equilibrium, and thus, just as in the case of Y , the sign of $(m-A)$ determines whether r approaches equilibrium from above or below. From the third period on, as it turns out, both Y and r are approaching equilibrium from the same side (both either rising or falling), even though their equilibrium values may lie in opposite directions from their respective starting points.

The striking thing about the interest rate is its behavior in the first two periods. Its movement is by no means simply a mirror image of the movement of income. If m is significantly greater than zero, r takes a big jump in the first period regardless of how smoothly Y adjusts. This point stands out clearly when $m=A$. In this case, Y moves directly to equilibrium in the first period, but r does not. Instead, it overshoots (or moves away from) equilibrium in the first period, returning to equilibrium only in the second period.

Figure 3 illustrates the behavior of r for an increase in the money supply when $(b_1+b_2) < 1$. The adjustment is shown there as a downward adjustment because this direction of change corresponds to the upward adjustment of Y shown in the preceding two figures. In general, the behavior of r is very similar if $(b_1+b_2) > 1$. The only essential difference is that the dotted equilibrium line lies above the origin; the interest rate still moves down at first and then back toward the equilibrium line.

III. *Economic Explanation*

This surprising behavior of income and the interest rate in a simple lag model has, in fact, a very simple economic explanation. The key lies in the function of the interest rate as the variable that clears the money market.

Assume for the moment that there is no distributed lag in the money-demand function; $m=0$ in equation (4). Even in this case, the interest rate must overshoot its new equilibrium position as soon as the money supply changes if there is any lag in the adjustment of Y . We have assumed that the money market is continuously cleared, and therefore aggregate money demand, M^* , must always change immediately by the same amount as any change in the money supply. Changes in Y and in

both contribute independently to the adjustment of M^* , but if Y changes gradually, its effect on money demand is felt only gradually. Initially, it has a small impact on money demand because only a portion of the total adjustment in Y has occurred. This throws onto r a part of the adjustment burden that will later be borne by Y , and thus it overshoots at first in compensating for the lag in Y .⁵

FIGURE 3. TIME PATH OF INTEREST RATE ADJUSTMENT
(Ratio of accumulated change to total equilibrium change, with $m=0.7$)

A lag in the demand for money has the independent effect of magnifying the movements of r . The coefficient of r in equation (4) is smaller, the greater is m . In other words, the *current* value of r has a smaller and smaller influence on the demand for money as the lag coefficient increases. Therefore, a given change in r this period causes less change in M^* if there are lags than if there are none. But M^* must in any case change by the amount of the change in the money supply, and there-

⁵ When $(b_1 + b_2) > 1$, r moves away from equilibrium at first rather than overshooting. This is identical both in cause and in consequences to the overshooting that occurs when $(b_1 + b_2) < 1$.

fore if there are lags, r must change by a greater amount initially in order to clear the money market. Similarly, lags reduce the coefficient of Y , and this reduces the effect a given change in current Y has in adjusting M^* and throws a greater adjustment burden initially on r , thereby increasing still more the amount it must change.

Changes in the interest rate influence income through their impact on investment. Of course, vigorous overshooting of the interest rate need not necessarily imply any corresponding immediate response by investment and income, in general. However, a crucial property of the lag formulation of investment demand being studied here lies in the fact that the lag is distributed, not discrete. Investment may depend relatively more heavily on past values of r , but at the same time it depends, to some small degree, on the current value of r . This small linkage gives r the direct tie it needs.

In this model, the initial response of I^* to any change in r is strictly proportional to the change in r . Thus, if r overshoots sufficiently far beyond its new equilibrium, it can cause I^* to overshoot immediately as well, operating solely through this small tie between I^* and current r . A sufficiently vigorous response by I^* will, in turn, carry Y to or beyond its equilibrium.

IV. *Empirical Relevance*

Despite the model's obvious inadequacies, simple curiosity demands that we plug into it some representative parameter values from empirical studies of U. S. data just to see what comes out. The theoretical validity of these results is independent of any data, but their empirical significance depends on whether there is a genuine possibility that we may have to revise our conclusions about the speed of monetary policy in the real world. This, in turn, hinges on whether there may exist a substantial distributed lag in the demand for money. If m is close to zero, then previous conclusions about the speed of monetary policy, although shown to be based on an incorrect argument, will be vindicated in fact, and this analysis will have little empirical significance.

The elementary textbook Keynesian view is that a speculative demand for money stocks provides much of the interest responsiveness of the demand for money, and this by its very nature implies a very rapid adjustment to changes in interest rates. This explanation must be rejected as entirely inadequate. The speculator who operates regularly with significant quantities of money will find it unprofitable to hold money for more than a very short period of time. The rate of return on short-term debt instruments will pay the transaction costs of buying and selling them even if they are only held a few days, and the risk of capital loss on them is essentially zero. Thus, very little money is held for genuinely speculative purposes at any point of time in the real world.

The more modern theories of liquidity preference present a rather different and more convincing picture. One's cash balance is an inventory, and each economic unit has a decision rule (very often only vague and implicit) specifying the inventory of cash to be held for future expenditures, both foreseen and unforeseen. The storage cost of money is the opportunity cost from interest income foregone, and the gain from holding money is savings in transaction costs and lower risk of capital loss. The optimal inventory of cash is a decreasing function of the interest rate (the storage cost). The question of speed of adjustment of the demand for money is the question of how frequently economic units consult their decision rules on cash inventory and how quickly they can modify institutional arrangements that determine to some extent the minimum quantity of cash required. There is nothing in this theory to suggest instantaneous or even rapid response to interest rate changes that, from the point of view of potential lenders, may be entirely transitory.

A substantial distributed lag in the demand for money thus appears reasonable in principle, and, in addition, there is empirical evidence of its existence. In his recent estimates of money-demand functions based on quarterly data for the United States, Ronald Teigen [8] finds that aggregate demand for money only completes about 31 per cent of its adjustment to equilibrium in one quarter.⁶ In a more recent paper, de Leeuw [4] finds even greater lags in money demand. Without attempting to evaluate their reliability, I have used Teigen's results and the investment function estimates of Kareken and Solow in [3] to derive the following parameter values for my model:^{7,8}

$$\begin{aligned}d &= -10.1 & j &= 0.550 \\f &= 0.178 & m &= 0.686 \\g &= -3.39\end{aligned}$$

Their data are quarterly, and thus I take one quarter as the length of each time period in my model. Note that investment demand responds

⁶ Teigen uses a lag function for the demand for money that is similar to equation (4) in this paper, and he finds a coefficient of 0.686 for M_{t-1} [8, p. 489, equation 3.1a]. This implies that adjustment is 31.4 per cent complete after one quarter.

⁷ The static equilibrium equation implied by Teigen's model [8, p. 491] has the property that $dM/dY = .1958 - .0080r$, where r is the rate on 4-6 month prime commercial paper. The 1948-58 average of r is 2.25, whence it follows that $f = 0.178$. In the same equation, $dM/dr = -.0080Y$. The 1948-58 average of GNP in billions of 1963 dollars is $Y = 424$, and making this substitution yields $g = -3.39$.

⁸ Kareken and Solow report [3, p. 38] an interest elasticity of equilibrium investment demand of approximately 0.5. Therefore, we have $dI/dr = -0.5I/r$. The 1948-58 average of gross private domestic investment in billions of 1963 dollars is $I = 64.6$. Kareken and Solow used Moody's industrial bond yields for their interest variable, and the 1948-58 average of this variable is 3.21. Accordingly, $d = -10.1$. Their estimate of the coefficient of I_{t-1} is approximately 0.55 [3, p. 37].

rather slowly, also, although not so slowly as the demand for money. Rather than find estimates for b_1 and b_2 , I have tried several possible values for their sum. The parameter values are substituted into equations (7) and (12), and the results are shown in Table 1.

In spite of the long lags in the investment and money-demand functions, it turns out that aggregate income adjusts to within 10 per cent of equilibrium within one quarter if (b_1+b_2) lies between 0.89 and 1.05, and for any smaller value it overshoots equilibrium by more than 10 per cent. The range between 0.89 and 1.05, furthermore, is about where we would expect to find (b_1+b_2) . Any value greater than 1.0 implies that the equilibrium interest rate is raised by expanding the money

TABLE 1—DYNAMIC ADJUSTMENT OF INCOME TO MONEY-SUPPLY CHANGES IN U.S.
Accumulated change in Y expressed as a ratio to equilibrium change in Y

Value of (b_1+b_2)	.70	.80	.90	.95	1.00	1.10	1.20
Implied value of A	.596	.626	.660	.678	.698	.740	.787
Accumulated adjustment after:							
1 quarter	1.288	1.190	1.084	1.025	.963	.829	.677
2 quarters	1.172	1.119	1.056	1.017	.975	.874	.746
3 quarters	1.102	1.075	1.037	1.012	.982	.907	.800
4 quarters	1.061	1.047	1.024	1.008	.987	.931	.843
5 quarters	1.036	1.029	1.016	1.005	.991	.949	.876
6 quarters	1.022	1.018	1.011	1.004	.994	.962	.902

supply and is lowered when M is reduced (the case of an upward-sloping IS curve in the Hicksian LM - IS diagram), and this is not particularly plausible. Yet, we must assign to b_2 , the marginal propensity to consume, a minimum value of at least 0.70, and only a moderate value for b_1 brings their sum close to 0.89.

The results are sensitive to the values of the lag coefficients j and m , and the standard errors of the estimates I have used are not small. Increasing j and decreasing m respectively by only one standard error, for example, leads to a model in which income does not overshoot for any of the values of (b_1+b_2) shown in Table 1, and with $(b_1+b_2)=1.0$, it takes seven quarters for income to approach within 10 per cent of equilibrium.

Thus, this little numerical exercise proves nothing, but it should certainly whet some appetites. The lag coefficients appear to be of the right order of magnitude, at least, to suggest the possibility that the money-demand lag may offset completely the influence of distributed lags in investment and consumption demand. Can more sophisticated methods confirm this? If so, the theoretical explanation for the apparent

slowness of monetary policy in the real world will have to be found elsewhere from now on, perhaps in such things as production lags or gradual revisions of expectations in response to monetary changes. Or perhaps monetary policy works more quickly than we thought.

V. Summary and Conclusion

The speed with which the economy responds when the monetary authority changes the money supply clearly depends directly on the speed with which investment responds to changes in the interest rate and other variables. The relation between them is not simple, however. In a linear model in which the behavioral equations have distributed lags and in which the money and product markets are cleared in every period, the interest rate, in performing its function of clearing the money market, will overshoot its new equilibrium as soon as the money supply changes. Furthermore, the longer the distributed lag in the demand for money, the greater the amount by which the interest rate will overshoot. If it overshoots far enough, it will cause both investment and income to overshoot, as well. The speed with which income adjusts to equilibrium depends partly on the length of the investment lag, but it also depends, in a general sense, on the difference between product-demand and money-demand lags. If there is little lag in the demand for money, then a long investment lag implies slow adjustment. No matter how long the product demand lags, however, adjustment is very rapid if the money-demand lag is comparably long.

The model is an unrealistic one, and this analysis clearly, then, does not show that monetary policy works quickly. Its significance, instead, is in pointing out the fallacy in a common argument purporting to show that monetary policy works slowly. Slow lagged response of investment to interest rate and income changes is not a sufficient condition for monetary policy to work slowly.

Yet, although the model as a whole is specific and unrealistic, the underlying economic mechanism that accounts for the results is completely general. A distributed lag in the demand for money will amplify the dynamic response of both the interest rate and income in almost any model in which the relations between variables are smooth and in which investment depends on the interest rate. The function of the interest rate as the variable that adjusts to reduce excess demand or supply in the lending market causes this behavior regardless of the shapes of the functions and regardless of whether markets are cleared in every period. This, basically, is why the results of the specific model in this paper may be accepted as an insight into the workings of monetary policy in the real world.

"The" interest rate may, of course, be interpreted broadly as an index

or representative of the many different interest rates and other terms of lending contracts. In the real world, the components of this index may adjust at different rates, and, in particular, some could adjust very slowly without preventing the index as a whole from behaving as does "the" interest rate in the model. For example, Kareken's and Solow's finding [3, p. 5] that interest rates on bank loans to business adjust very slowly to equilibrium, a finding they use as additional evidence that investment must respond slowly to monetary policy changes, is logically consistent with rapid investment and income response. Major lags in the demand for money, such as found by Teigen [8], could cause market yields on government and corporate bonds and the nonmonetary terms of bank lending contracts to change rapidly, leaving quoted bank lending rates and time deposit dividend rates to follow behind months later. The rapid changes in bond yields and nonmonetary lending terms might be enough, by themselves, to cause rapid adjustment of investment spending and income.

These results provide an interesting commentary on the subject of indicator and target variables for monetary policy. Even when all behavioral parameters and exogenous variables other than the money supply itself remain fixed, the money supply and the interest rate do not move together in a simple way. Large interest rate fluctuations may be associated with monotonic money-supply adjustment, and they need not be taken as evidence of excessively abrupt or destabilizing monetary policy action. Also, a policy of linear adjustment of the interest rate to a new level is distinctly different from a policy of linear adjustment of the money supply to a new level.

Two additional lessons may be drawn from this study. In a general way, it shows that having the current value of some variable y depend on a weighted average of the values assumed by another variable x in several periods—rather than on the value of x in only one period, current or past—does not necessarily smooth out or damp the dynamic behavior of the system. The interaction of distributed-lag behavioral relations in a simultaneous system cannot be assumed to lead in a simple way to gradual lagged adjustment. The intuition that expects gradual adjustment is a poor guide.

Finally, this work should demonstrate that analysis and estimation of dynamic investment response cannot be granted any position of unique importance in empirical work on the speed of monetary policy. The portfolio behavior of holders of liquid assets plays a role equally as influential, and major research efforts should be concentrated in the future on understanding the monetary side of individual and firm behavior.

THE EFFECTIVENESS OF AUTOMATIC STABILIZERS

By PETER EILBOTT*

Automatic stabilizers are fiscal or monetary mechanisms which automatically reduce the flow of income or money to individuals and corporations during periods of expansion and which increase such flows (relative to what they would have been in the mechanisms' absence) in times of recession. The corporate and personal income tax and the unemployment compensation program are examples of automatic stabilizers. Tax receipts rise and fall automatically as incomes fluctuate, and unemployment compensation benefit payments increase automatically in response to rising unemployment. (The fact that individuals must apply for benefit payments does not change their basic automaticity.)

The stabilizers represent an important countercyclical force, since they avoid the difficulties which beset discretionary policy—difficulties arising out of problems of timing and errors of judgment. There have been numerous attempts to measure their quantitative impact in the postwar period as a guide to determining their role in countercyclical policy. With few exceptions, however, these investigations determined only the response of changes in taxes and transfer payments to given increases or decreases in national income.

Thus Hart [7], Clement [1], Lewis [9], and Duesenberry, Eckstein, and Fromm [5] all evaluated the built-in flexibility of the automatic stabilizers (that is, the response of the various stabilizing items to changes in national income), the first three by examining historical data, the last by performing a simulation study. Similarly, Lester [8], Pechman [15], and others cited in the bibliography [2] [3] [16] investigated the response of individual stabilizers to changes in national income. Finally, Creamer [4] computed the value of recession-generated unemployment benefit payments and recession-induced personal income tax reductions, and Ida Merriam [11] computed the value of recession-generated social insurance payments—that is, the amounts paid out over and above the amounts which would have been paid in the absence of the recession.

* The views expressed in this article are those of the author, and do not necessarily reflect the views of the New York Stock Exchange, where he is employed as a research economist. He wishes to acknowledge the very helpful comments of Professor James W. Angell, both on the draft of this article and on the dissertation [6] from which the article is drawn.

A change in income will lead to a change in taxes, and it is clearly useful to know how income changes affect both the sums paid out in benefit payments and the taxes collected from individuals and corporations. It seems even more important, though, to determine how tax and transfer payment changes affect private spending and therefore movements in national income—in other words, to determine the percentage of potential income changes prevented by the stabilizers during recessions and expansions.

While a few studies have examined the effectiveness of the stabilizers from this point of view, these studies were based on limited historical data. Thus, Musgrave and Miller [12] employed a rather simplified multiplier model to investigate the effectiveness of the stabilizers in 1947-48 (Musgrave [13] later employed the same model to measure the stabilizers' impact in the mid-1950's). Lusher [10] employed a different model to examine data from the 1930's and to evaluate the stabilizers' effectiveness in a hypothetical recession occurring in the mid-1950's. Finally, Pearse [14] developed a model somewhat similar to ours to measure the impact of the British tax stabilizers.¹

In this article we evaluate the effectiveness of the stabilizers in reducing income changes during the postwar period. Specifically, we will estimate, on the basis of a multiplier model, by what percentage the stabilizers reduced the potential change in income in each of the three recessions and three expansions between 1948 and 1960.² We are primarily concerned with the stabilizers' countercyclical role and not with their effect on economic growth. Consequently, a tax which restricts a rise in income is designated a stabilizer, though it may be inhibiting from the point of view of growth. However, as pointed out in Section II. A, while the model depicts the stabilizing (or restrictive) effect of taxes and transfer payments during the postwar expansions, in practice rising government expenditures largely offset this effect. As a result, growth was generally not inhibited by the stabilizers.

I. The Model and Its Application

Our model is basically an elaboration of the one first developed by Musgrave and Miller (and repeated by Musgrave in *The Theory of Public Finance* [13 pp., 509-11]). In their formulation

¹ Pearse's article appeared in 1962 and was apparently written at approximately the same time as the dissertation on which this article is based.

² While it was also our intention to evaluate the impact of the stabilizers in the 1960-61 recession, the decline in national income was too limited to permit meaningful results. Thus, Lewis found that taxes decreased by 97 per cent of the decline in GNP occurring during the contraction, while unemployment benefit payments increased by 25 per cent of that decline [9, p. 30]. The stabilizers therefore had a combined "swing" of 122 per cent of the reduction in GNP, and this result must be considered atypical.

$$\alpha = \frac{cEr}{1 - c + cEr}$$

where E is the combined income elasticity of personal and corporate taxes, r the ratio of these taxes to national income, c the marginal propensity to consume out of disposable income plus retained corporate earnings, and α the percentage of a potential change in income prevented by the stabilizers.

By introducing a new term allowing for a change in consumption in response to a change in transfer payments and, more important, by separating the corporate from the personal sector, we have developed the following model (whose derivation is available on request):

$$\alpha = \frac{c(E_r r_1 - E_\mu \mu_1) + i(E_t t_1)}{1 - c \frac{\Delta X}{\Delta Y} - i \frac{\Delta Z}{\Delta Y} + c(E_r r_1 - E_\mu \mu_1) + i(E_t t_1)}.$$

E_r , E_μ , and E_t are, respectively, the income elasticities of personal taxes, transfer payments, and corporate taxes; r_1 , μ_1 , and t_1 are the ratios of personal taxes, transfer payments, and corporate taxes to national income at the beginning of the period under analysis; c is the marginal propensity to consume out of disposable income; i is the marginal propensity to invest out of retained corporate earnings; $\Delta X/\Delta Y$ and $\Delta Z/\Delta Y$ are the personal and corporate shares of a change in national income; and α is the percentage of a potential change in income prevented by the stabilizers. In contrast to Musgrave and Miller's model, our formulation relates consumption directly to personal taxes and the noncorporate part of national income, while investment is related only to corporate taxes and the corporate share of national income.

The combined impact of the following items, which are commonly designated automatic stabilizers, is tested by our model: individual income taxes, corporate taxes, excise taxes, unemployment compensation benefit payments and contributions, and Old Age and Survivors Insurance benefit payments and contributions.⁸ Because of the difficulty of adjusting some of the data for changes in tax rates and lags in collections, certain components of these taxes and transfer payments

⁸ Results which exclude the impact of the OASDI program are also presented, since its characterization as an automatic stabilizer may be disputed. In addition, benefit payments and contributions could not be adjusted for the extensive increases in coverage occurring in the postwar period. As a result, they both show a fairly continuous growth, even when adjusted for the effects of rate and benefit payment changes and for increases in the taxable wage base.

are excluded from the analysis. As a result, only the following data are employed:

Individual taxes. Personal income tax withholding collections, federal excise taxes (considered personal income taxes assessed on an expenditure basis), and personal OASDI contributions (excluding payments by the self-employed).

Corporate taxes. Corporate income tax accruals (excluding excess profits tax accruals in 1950-53), unemployment contributions to state unemployment trust funds, and corporate OASDI contributions.

Transfer payments. Unemployment benefit payments (excluding payments under temporary programs) and OASDI benefit payments.

Our basic data consist of the quarterly values of these taxes and transfer payments during the years 1948 through 1960, covering three complete recessions and three complete expansions. We determine the effectiveness of the stabilizers during each recession and each expansion, and also measure their average effectiveness. In addition, we evaluate the impact of the tax stabilizers both on the basis of historical data and, where rates changed over time, on the basis of data adjusted to 1965 tax rates.

Before the available tax and transfer payment data can be employed in our model, several adjustments are necessary (a detailed explanation of these adjustments is available on request, as are the final adjusted data).

1. *Adjustment for a collections lag.* The individual bears the impact of a tax payment when he makes that payment. Most published data, however (except for accrual data), reflect receipt of the funds by the government. This may occur months after the taxes are withheld by an employer or collected by a business establishment. If the impact of the stabilizers is to be attributed to the proper time period, an adjustment must be made for this delay.

2. *Adjustment for the effects of statutory rate and benefit payment changes.* The analysis involves comparisons of tax collections and transfer payments at the beginning and end of specific recessions and expansions. If no adjustment is made for a tax rate increase occurring during an expansion, the rise in national income would appear to have caused a sizable increase in tax collections, and the effectiveness of the stabilizers would be overstated. The impact of the OASDI program would also be overstated if no allowance were made for a statutory increase in benefit payments occurring during a recession. The data must therefore be adjusted for the effects of rate and benefit payment changes.

3. *Adjustment of the tax series to 1965 tax rates.* The various tax series are also adjusted to 1965 rates in an attempt to appraise the quantitative importance of the present set of automatic stabilizers. For example, since corporate tax rates have been increased considerably since 1948, estimates of the stabilizers' current effectiveness cannot be based on the response of corporate taxes to the decline in national income during the 1948-49 recession. We can, however, estimate how corporate taxes would have changed in 1948-49 had present rates then been in effect, and use these data in the model.

Unemployment and OASDI benefit payments and contributions are not brought up to recent levels, however. Benefit payments are expressed in absolute amounts, and not in percentages, as are tax rates. These payments have risen steadily in response to the inflation and the rise in real wages which have characterized the postwar period, and they now bear no reasonable relation to payments made in previous years. It therefore seems meaningless to estimate how effective benefit payments would have been ten or fifteen years ago had current payment levels then been in effect. Since changes in unemployment and OASDI contribution rates have reflected, in part, the rise in benefit levels, contributions are also not adjusted to present rates.

4. *Adjustment for the effects of seasonal influences.* The data are seasonally adjusted in order to establish the relationship between changes in national income and changes in taxes and transfer payments in a form independent of a particular time of year. The seasonal factors are based on data from years not marked by rate changes, and on data adjusted for these changes where tax rates were revised frequently.

The data are not adjusted for changes in the price level. An increase in tax revenues, assuming a given tax structure, is the same whether the increase in national income which gave rise to it reflects inflation or is a result of real factors (ignoring the possibility of differential effects on the distribution of income under the two sets of circumstances).

By applying the model to the adjusted data we obtain our estimates of the effectiveness of the stabilizers in restricting changes in income. As a first step, we derive income elasticities by computing the percentage changes in individual taxes, corporate taxes, and transfer payments between the initial and terminal quarters of each recession and each expansion, and by determining the ratios of these percentages to the percentage changes in national income occurring within the same periods.

The resulting elasticities are arc elasticities, which apply only to a

period as a whole. Consequently, if the calculations indicate that the stabilizers prevented 40 per cent of a potential rise in income during an upswing, the percentage measures the stabilizers' effectiveness only over the complete expansion. It may also, however, be considered a measure of the average effectiveness of the stabilizers during the upswing.

As a second step, we calculate the ratios of tax collections and transfer payments to national income in the initial quarters of each recession and each expansion. The use of these quarters follows from the derivation of the model, in which the stabilizing impact of a tax is a function of its arc elasticity from the initial to the terminal quarter of a particular period, and of its ratio to national income in that initial quarter.

Third, the ratios $\Delta X/\Delta Y$ and $\Delta Z/\Delta Y$ are derived by relating the change in pretax retained corporate profits (net of inventory profits and losses) and in corporate social insurance contributions during each upswing or downswing to the change in national income occurring within the same period. This calculation yields $\Delta Z/\Delta Y$, and $\Delta X/\Delta Y$ is derived simply by subtracting $\Delta Z/\Delta Y$ from 1.

Finally, the values of the various income elasticities, the ratios of taxes and transfer payments to national income, and the ratios $\Delta X/\Delta Y$ and $\Delta Z/\Delta Y$ are employed with several combinations of assumed values c and i , in the manner prescribed by the model, to derive the estimates of α . The resulting values represent the percentages by which the stabilizers reduced the potential change in income during each recession and expansion.

Since estimates of the values of c and i in the postwar period vary, several combinations of values of these variables are employed in the calculations. These values (0.8, 0.85, and 0.9 for c ; and 0.3, 0.4, and 0.5 for i) span the range of existing estimates, and their use in different combinations permits a determination of the stabilizers' effectiveness under varying assumptions. Estimates of α resulting from the use of other values of c and i are presented in Chart 1.

The use of fixed values of c and i does not imply that these variables were stable during the postwar business cycles. Since the results obtained by using the model represent the *average* effectiveness of the stabilizers during a given period, the values assigned to c and i may be considered averages of the values these variables assume during that period.

Table 1 illustrates the calculations involved in deriving the values of α (using data from the 1957-58 recession). Table 2 presents these values for each contraction and each expansion, on the basis of data adjusted to tax rates existing at the beginning of each period and

adjusted to 1965 tax rates. In addition, the table presents estimates of α derived from the average values, over the three recessions and three expansions, of the various income elasticities and ratios of taxes and transfer payments to national income. These estimates, based only on data adjusted to 1965 tax rates, may be assumed to represent the best appraisals of the present effectiveness of the stabilizers. They are portrayed in Chart 1, though on the basis of a considerably wider range of values of c and i than are employed in Table 2.

Table 2 also presents results which exclude the impact of both OASDI contributions and benefit payments. Only selected combinations of c and i are employed in the calculations, which are based on data adjusted to 1965 tax rates.

II. Interpretation of the Results

A. The Impact of the Stabilizers

Table 2 indicates that, during the three recessions between 1948 and 1960, the stabilizers would have prevented an average of from 36 to 52 per cent of the income declines which would have occurred in their absence had 1965 tax rates been in force. According to the tax changes which actually occurred, they were slightly more effective, since tax rates were higher than they are now in two of those recessions. To discuss the average impact of the stabilizers in terms of historical tax rates is meaningless, though, since rate revisions were partly responsible for the changes in their effectiveness between the various recessions.

Table 2 also shows that the impact of the stabilizers varied considerably from recession to recession. They were most effective during the 1953-54 downswing, when they reduced the potential decline by from 42 to 58 per cent, and would have reduced it by from 41 to 56 per cent had 1965 tax rates been in force.

The discussion is framed in terms of ranges of effectiveness, since we do not attempt to determine the actual values of c and i during the period covered by the analysis. Nevertheless, we assume that these values did in fact fall between the limits employed in the calculations.⁴

⁴ As noted previously, Chart 1 portrays estimates of the stabilizers' effectiveness based on a considerably wider range of values of c and i than are employed in Table 2.

The findings indicate that, even if one assumes fairly low values for the two marginal propensities, the stabilizers prevented an average of over one-third of the potential income declines during the first three postwar recessions. On the other hand, if the average values of c and i were at the upper limits employed in the calculations, those declines would have been twice as severe in the absence of the stabilizers.

The stabilizers were somewhat less effective during the three expansions between 1948 and 1960 than they appear to have been during recessions (measuring effectiveness in terms of a dampening of a rise in income). Table 2 indicates that they would have reduced the potential increases in income by an average of from 25 to 42 per cent had 1965 tax rates been in force, while their impact on the basis of actual tax changes was slightly greater. The stabilizing percentages show relatively little variation from expansion to expansion.

It must be pointed out that the values of α for expansions do not necessarily indicate the actual effectiveness of the stabilizers during the particular periods. The model assumes that the stabilizers have no impact on government spending on goods and services; this assumption is implicit in the derivation of α . Consequently, if government expenditures increased in response to (or along with) the stabilizer-induced rise in revenues (as they generally did during the postwar expansions), the data would only depict how effective the stabilizers might have been had government spending on goods and services remained unchanged, and not their actual effectiveness during the particular upswings.

The data indicate that the stabilizers have an impact in recessions which differs only moderately from their impact in expansions. Previous studies, which measured the response of taxes and transfer payments to changes in national income, showed that the stabilizers were substantially more effective during recessions. The conflict may be resolved in the following terms.

How effective the stabilizers are depends on their impact on the economy's over-all marginal propensity to save out of national income (considered as some kind of weighted average of the individual, corporate, and government sectors' marginal propensities to save). That is, because of the stabilizers, the government's budget (including trust fund operations) is pushed toward a surplus during periods of rising national income. As a result, the government becomes a net saver, thereby raising the economy's marginal propensity to save out of national income. Similarly, the budget is pushed toward a deficit during recessions, and the over-all marginal propensity to dissave is increased.⁶

⁶ For the rest of this article, the terms marginal propensity to save and to spend will be applied both to expansions and to contractions, though it would be more appropriate to refer to dissaving and dissaving during periods of income decline.

Since the value of the system's multiplier is a reciprocal of the marginal propensity to save (hereafter referred to as the m.p.s.), the stabilizers, through their impact on the m.p.s., dampen the multiplier.

The reduction in the value of the multiplier depends not only on the absolute increase effected by the stabilizers in the m.p.s., but also on that propensity's initial value. For example, the stabilizers reduce the value of the multiplier from $3\frac{1}{3}$ to $2\frac{1}{2}$, and diminish potential income changes by 25 per cent if they increase the m.p.s. from 0.3 to 0.4. If they raise its value from 0.1 to 0.2, they lower the multiplier from 10 to 5 and dampen income changes by 50 per cent. Consequently, the lower the m.p.s., the greater the impact of a given set of stabilizers.⁶

The evidence indicates that a considerably higher marginal savings rate has characterized the postwar recessions than the postwar expansions. The corporate sector absorbed the major share of declines in national income, and maintained dividend payments virtually unchanged in the face of these declines. This corporate absorption led to a fairly high over-all marginal savings rate, since the marginal propensity to invest out of retained earnings is assumed to be considerably lower than the marginal propensity to consume out of disposable income.

During expansions, on the other hand, the corporate sector absorbed a much smaller share of the over-all increases in income, and also raised its dividend payments substantially. The marginal savings rate was therefore considerably lower, *on average*, permitting the stabilizers, which produced a much smaller absolute increase in that savings rate,⁷ to have a sizable impact.

The above argument may be reformulated in the following way. Assuming that additional forces would not have depressed the economy had the stabilizers been inoperative, the postwar recessions would have been relatively mild even in the absence of the stabilizers (because the corporate sector would have provided a cushioning impact until the forces stimulating growth reasserted themselves). Therefore, recessions which would not have been very severe in the stabilizers' absence were made even milder by their presence. During expansions, on the other hand, the absorption by the individual sector of the bulk of changes in national income implies a sizable potential response to autonomous changes in investment (or in some other factor). The impact of what seems to be, on the basis of an analysis of built-in flexibility, a less effective set of stabilizers is thereby enhanced.

⁶ This explains why the effectiveness of the stabilizers varies directly with the assumed values of c and i —the higher these values, the lower the m.p.s.

⁷ The finding that the stabilizers caused a smaller increase in the m.p.s. during expansions than during recessions derives from those previous studies which measured the response of taxes and transfer payments to changes in national income.

B. The Impact of the 1964 Tax Revision

A comparison of the results based on historical data with those based on data adjusted to 1965 tax rates indicates that the 1964 tax revisions should have only a slight impact on the effectiveness of the stabilizers during recessions, but a somewhat greater impact during expansions. The values of α during the 1957-58 recession and the 1954-57 and 1958-60 expansions are employed in this comparison, since these were periods with an 18 per cent withholding rate and a 52 per cent corporate tax rate.

Table 2 shows that the stabilizers reduced the income decline by 34.6 to 49.9 per cent during the 1957-58 recession. They would have reduced the decline by 32.8 to 47.9 per cent had 1965 tax rates been in force, lowering their effectiveness by about 5 per cent in relative terms. During the 1954-57 and 1958-60 expansions, however, the stabilizers would have been up to one-sixth less effective had 1965 tax rates been in force. Thus, while they prevented from 26.7 to 44.3 per cent of the potential rise in income during the 1954-57 expansion, when the withholding rate was 18 per cent and the corporate tax rate 52 per cent, they would have prevented from 22.5 to 39.5 per cent of that rise had the withholding rate been 14 per cent and the corporate tax rate 48 per cent (as already noted, the percentages only show the stabilizers' potential impact, since government expenditures were not held constant during the period).

The 1964 tax revisions affected mainly the individual income tax, and this explains their greater impact on the stabilizers during expansions. As long as the corporate sector bears the brunt of an income decline, the substantial personal tax reduction cannot lead to more than a small diminution of tax sensitivity during downswings.

From the point of view of economic growth it is desirable that tax changes should lessen the impact of the stabilizers during expansions and not during contractions. Growth considerations therefore suggest that future tax reductions should be concentrated in the individual rather than in the corporate sector.

C. Exclusion of the OASDI Program

When the effects of the OASDI program are excluded from the calculations, the effectiveness of the stabilizers is reduced during recessions and enhanced during expansions. This reflects the steady rise in benefit payments throughout the postwar period, even when payments are adjusted for statutory increases in benefit levels. Consequently, the OASDI program has been stabilizing during contractions and destabilizing during expansions (taking into account both payments and con-

tributions). This pattern is likely to persist as long as the number of persons receiving benefits continues to increase, in response to both statutory changes and the rapid growth in the number of older persons.

III. *Summary and Conclusions*

Whether the average values of c and i are at the upper or at the lower limits employed in the calculations, the stabilizers are clearly a powerful tool for dealing with cyclical fluctuations. Other things being equal, they will reduce declines in national income by about 50 per cent if the values of c and i are close to 0.9 and 0.5, respectively. They are in fact likely to have a somewhat greater impact however. In their absence the economy might be subject to even greater downward pressures than the model indicates, since psychological factors (which are not taken into account in the model) might then become adverse. In addition, a stabilizer-induced budget deficit will probably be financed in an expansionary manner.

The effectiveness of the stabilizers would be further increased by a strengthening of the unemployment compensation system. If all employees were covered, if benefit levels were raised to 50 per cent of the average weekly wage of covered workers, and if payments were extended to a uniform period of 26 weeks, benefit payments during recessions of postwar severity would be increased by about 100 per cent.⁸ The effectiveness of the stabilizers would then be almost 10 per cent greater in absolute terms, enabling them to prevent 60 per cent of a potential decline in national income.

During expansions, the stabilizers would prevent over 40 per cent of potential increases in income if the average values of c and i were close to 0.9 and 0.5, respectively, and if government spending on goods and services remained unchanged. In fact, though, much of the stabilizers' impact was offset by rising government expenditures during the postwar period, though there is no indication that this reflected deliberate government policy.

If the average values of c and i are at the lower limits employed in the calculations, the stabilizers would prevent about 35 per cent of a potential income decline during recessions and close to 45 per cent if the unemployment compensation system were strengthened. During periods of expansion they would reduce a potential rise in income by about 25 per cent.

⁸ For the calculations on which this conclusion is based, see my unpublished dissertation [6, pp 221-25].

Provisions for the automatic extension of the duration of unemployment benefits, while also desirable, would have a very limited impact on the stabilizers. They would tend to go into effect only towards the end of a recession.

In general, while different observers will judge the effectiveness of a given countercyclical tool by different standards, the stabilizers do appear to provide, under all but unusual circumstances, a reasonably satisfactory defense against downward pressures on the economy.⁹ They do not suffer, as do discretionary policies, from problems of timing and errors of judgment, and they seem to be powerful enough (especially if the unemployment compensation system is strengthened considerably) to prevent a substantial percentage of an income decline. Their operations can easily be supplemented by antirecessionary monetary policies, and by cuts in the withholding rate if a recession gives no sign of slackening some specified time period after the previous peak.

The stabilizers do not appear to be as useful a tool during periods of expansion, however. They exercise a fairly strong restraining influence, which must be offset, at least in part, by tax reductions or by increased government spending.

⁹ They obviously would not be able to deal, though, with the problems created by the existence of depressed areas or technological unemployment. These problems would require specific measures—such as job retraining and relocation allowances—for their solution.

COMMUNICATIONS

Tariff Reductions and Trade in Manufactures among the Industrial Countries

This paper uses empirical evidence to examine the proposition advanced by Lawrence B. Krause that the establishment of the Common Market will seriously harm U.S. exports because "dominant suppliers"¹ in EEC countries receive increased protection from the averaging of national tariffs [5] [6]. Subsequently, the results are used to reinterpret the traditional conclusions regarding the effects of tariff reductions on the domestic economy, and additional tests are offered to indicate the predominance of intraindustry—as against interindustry—specialization in trade in manufactures among the industrial countries.

I

Upon finding that, in the case of dominant suppliers, national duties are generally lower than the common external tariff, Krause claims that "a comparison of the new EEC tariff for each commodity group with the former national tariff of the leading exporting country in intra-Community trade of each product gives the vivid impression that the new EEC tariff is much more protective than the old national tariff" [6, p. 101-2]. Now, under the assumption that "the expansion of the output of these suppliers will not significantly change their average costs" [6, p. 101], Krause reaches the conclusion that the dominant suppliers present a threat to foreign—and particularly to U.S.—exporters in the markets of the partner countries.

I have elsewhere criticized Krause's argument and noted that the effects of the Common Market on imports from third countries should properly be considered in two steps: (a) the implications of the averaging of national tariffs, and (b) the discriminatory effects of eliminating duties on intra-EEC trade. The averaging of tariffs *by itself* is likely to reduce, rather than increase, protection in the European Common Market: low-cost dominant suppliers who compete in the world market will receive greater—but largely unnecessary—protection while the lowering of duties will expose high-cost producers to foreign competition.² Further, I have expressed doubts about the possibility of dominant suppliers being able to expand output at constant costs to exploit the possibilities offered by tariff discrimination and to replace third-country exporters in the markets of partner countries [1].

With data available for several years since the creation of the EEC, it is now possible to test empirically the validity of Krause's hypothesis. Since, after the lowering of tariffs in the partner countries, dominant suppliers would first increase their sales at the expense of partner-country producers, Krause's

¹ The expression "dominant supplier" denotes the largest exporter in intra-area trade within each commodity category prior to the formation of the EEC.

² A similar argument has recently been made in [4].

TABLE 1—MARKET SHARES OF DOMINANT SUPPLIERS^a IN INTRA-EEC EXPORTS FOR 91 MANUFACTURING INDUSTRIES

(Per cent)

Intra-EEC exports in 1958	Common Market	Belgium	France	Germany	Italy	Netherlands
Combined share of dominant suppliers ^b	51.0 (91) ^c	46.2 (22)	15.5 (8)	84.2 (50)	18.1 (5)	12.6 (6)
Combined share of second largest suppliers	21.8 (91)	33.8 (23)	36.3 (21)	5.3 (17)	18.3 (9)	40.5 (21)
Combined share of two largest suppliers	72.8 (182)	80.0 (45)	51.8 (29)	89.5 (67)	36.4 (14)	53.1 (27)
Increment in intra-EEC exports between 1958 and 1963						
Combined share of dominant suppliers	39.5	33.1	6.9	78.6	8.8	13.7
Combined share of second largest suppliers	17.0	31.7	18.9	5.6	13.7	36.7
Combined share of two largest suppliers	56.5	64.8	25.8	84.2	22.5	50.4

^a The largest exporters in intra-EEC trade within each commodity category in the year 1958

^b The combined share of the dominant suppliers in the intra-EEC exports of the individual member countries, or the six countries taken together.

^c Numbers in parentheses refer to the number of suppliers in each category.

hypothesis should be accepted or rejected, depending on whether the share of dominant suppliers in intra-EEC trade has increased or declined following the Common Market's establishment.

For purposes of the investigation, I have divided the Common Market manufacturing sector into 91 industries and have considered changes in intra-EEC trade between 1958 and 1963. The general principle of classification has been to group together products that have a high degree of substitutability in production, although the limited availability of data has often constrained our choices. In 56 cases the categories utilized correspond to three-digit SITC items, in 28 instances a four-digit breakdown has been used, and seven categories involve combining two or more three-digit items.⁸

The results shown in Table 1 indicate that the share of dominant suppliers in intra-EEC trade declined in the period 1958-63. Thus, while the dominant suppliers in individual industries, taken together, accounted for 51.0 per cent of trade among the Common Market countries in 1958, their share in the in-

⁸ A similar classification has been used in [3].

crement of intra-area trade between 1958 and 1963 was only 39.5 per cent. It should be emphasized that this decline is not explained by changes in the identity of the dominant suppliers between 1958 and 1963, since the largest exporters in intra-area trade in 1963 provided 45.9 per cent of exports in that year, as compared to 43.4 per cent furnished by the dominant suppliers of the year 1958.

The conclusions hardly change if industry-by-industry comparisons are made. Dominant suppliers accounted for over one-half of trade among the Common Market countries in 52 out of the 91 industries in 1958, but their share in the increment of trade between 1958 and 1963 exceeded 50 per cent in 20 industries only. Moreover, among the 84 industries where intra-EEC trade expanded during this period, an absolute reduction in the exports of any one country is observed in only twelve cases; of these, the decline pertains to more than one country in two instances. Finally, considering the two largest suppliers within each industry, we find that their combined share declined from 72.8 per cent in 1958 trade to 56.5 per cent in the increment of intra-EEC trade during the period under consideration.

Similar results are obtained if we examine the export performance of the dominant suppliers in each of the five member countries. The data of Table 1 show a decline in the share of these suppliers within the intra-EEC exports of every country, the only exception being the Netherlands. The Dutch sample is rather small, however, since in 1958 the Netherlands was ahead in only six industries. And Dutch producers, too, follow the general pattern if the two largest exporters are considered in every industry, or if changes in the shares of dominant suppliers in the intra-area exports of individual commodities are calculated.⁴

Thus, dominant suppliers have apparently lost ground since the establishment of the Common Market and we are led to reject Krause's hypothesis. This conclusion is not affected if the data are regrouped according to the industry classification employed by Krause. We find, then, that in the 20 industries he considered [6, p. 103]⁵ the dominant suppliers accounted for 56.4 per cent of intra-area trade in 1958, and their share in the increment of this trade between 1958 and 1963 declined to 40.9 per cent. Accordingly, it would appear that Krause has overestimated the ability of dominant suppliers to expand production at constant costs, and hence the chances of trade diversion.

II

Aside from their usefulness in judging the validity of Krause's hypothesis, these results have more general implications both for the theory of international specialization and for commercial policy. According to the familiar textbook exposition, multilateral reductions in duties would lead to a reallocation of resources from import-competing industries to export industries, accompanied

⁴ In the latter case, adjustment has been made for intercountry differences in the expansion of the total exports of manufactured goods.

⁵ We have excluded Miscellaneous chemicals and Manufactured goods, n.e.s., because these could not be identified with SITC categories.

by a contraction in the activity of the former and an expansion of the latter. Correspondingly, despite the ensuing improvements in productive efficiency, the welfare consequences of a move toward free trade are not unambiguous since—in the absence of appropriate compensation—the factors used more intensively in the production of importables would experience a decline in their real income.

The losses that import-competing industries might sustain in countries participating in multilateral tariff reductions have also received considerable attention in public discussions. The possible adverse consequences of lowering tariffs for particular industries have been emphasized by the opponents of entry into the European Common Market, especially in France and Italy, and arguments along these lines have recently been invoked in connection with the Kennedy-round of tariff negotiations. It would also appear that such fears have often slowed down the process of negotiations held under the auspices of GATT, and have limited the extent of reductions in duties.

Since, according to the traditional explanation, tariff reductions would be followed by interindustry specialization, the validity of this hypothesis requires that within each industry the largest supplier, or suppliers, of the preintegration period have the lion's share in the expansion of intra-area trade. Our results do not reveal such a tendency; instead of concentration, an increasing diversification in export patterns is indicated. Rather than increasingly specializing in industries where they had been leading exporters prior to the establishment of the European Common Market, the member countries have lost ground in these industries and have reduced reliance on them in expanding their exports.

It is suggested here that the failure of the traditional explanation stems from the inadequacies of conventional models that deal exclusively with standardized commodities. In the case of standardized goods, cost differences are the main determinants of trade, and a country cannot protect and export the same commodity. In such instances, the traditional conclusions on the reallocation of resources from import-competing to export industries follow: reductions in tariffs lead to a contraction in the former and an expansion in the latter.

Only a few manufactured goods (e.g., steel ingots, nonferrous metals, paper) traded among the industrial countries are standardized commodities, however, while the large majority are differentiated products that can be protected *and* exported. In the presence of national product differentiation, multilateral tariff reductions may lead to an increased exchange of clothing articles, automobiles, and other consumer goods, for example, without substantial changes in the structure of production. Further, the expansion of trade in machinery and in intermediate products at a higher level of fabrication, following all-round reductions in duties, may entail specialization in narrower ranges of products rather than the demise of national industries. These changes, then, would involve intraindustry rather than interindustry specialization.

While the results of the calculations constitute a rejection of the traditional explanation, they are consistent with the hypothesis that tariff reductions

would result in intraindustry specialization.⁶ This hypothesis receives further support from evidence pertaining to the pattern of intra-area exports of the Common Market countries and the relationships between exports and imports in the various industries of these countries.

To begin with, the calculations reported in Table 2 show a positive correlation between the structure of intra-area exports of the individual EEC countries. It is also apparent that the export patterns of these countries have become more uniform since the establishment of the Community. Thus, the rank correlation coefficients calculated with regard to 91 industries ranked by the value of intra-EEC exports are larger in 1963 than in 1958 for all pairs of

countries, with the differences amounting to at least one-fifth of the value shown for 1958. A shorthand expression of the results can be given if we consider that the unweighted average of the rank correlation coefficients rose from .53 to .67 in the period under consideration.

The increasing uniformity of export patterns in the EEC countries provides evidence that the creation of new trade among these countries as a result of the 50 per cent reduction in intra-area tariffs accomplished by 1963 has taken the form of intraindustry specialization.⁷ Another approach to the problem is to consider the relative magnitudes of the export (import) balances of individual countries for the 91 commodity categories. For this purpose, I have expressed the absolute difference between exports and imports in each category

* Similar conclusions have been derived for the Benelux union by P. J. Verdoorn [7] and for trade in machinery and precision instruments among the major industrial countries by the present author [3].

⁷ For an analysis of trade creation and trade diversion in the Common Market, see [2].

as a ratio of the sum of exports and imports and have calculated, for every country, an unweighted average of these ratios.⁸ Should interindustry specialization predominate, one would expect the resulting "representative ratios" to approach unity since a country would either export or import a commodity. By contrast, in the case of intraindustry specialization, the ratios would tend toward zero because exports and imports would tend toward equality within each category.

In the countries under consideration the relevant ratios were approximately in the .4 to .6 range in 1958 and .3 to .5 in 1963, indicating the relative importance of intraindustry specialization (Table 3). And while the figures

^a Calculated as unweighted averages of the ratio of the absolute difference of exports and imports to the sum of exports and imports for 91 industries by the use of the following formula:

$$\frac{1}{n} \sum \frac{|X_i - M_i|}{X_i + M_i}.$$

Source: See Table 1.

shown for a given country and a particular year are difficult to interpret, changes in these ratios over time permit us to draw inferences regarding the effects of tariff reductions on specialization. With the "representative ratios" falling in every country following the Common Market's establishment, one may conclude that reductions in duties have led to increasing intraindustry specialization in the EEC. Further, the higher values shown for Italy may be taken to indicate that intraindustry specialization increases with the development of manufacturing industry.

The results point to the importance of intraindustry specialization in trade among industrial countries and provide support to the hypothesis that trade liberalization would result in intraindustry rather than interindustry specialization. It follows that we have to revise the conclusions derived from traditional theory regarding the welfare consequences of tariff reductions.

⁸ The following formula has been used in the calculations:

$$\frac{1}{n} \sum \frac{|X_i - M_i|}{X_i + M_i}$$

where X_i and M_i refer to the intra-EEC exports and imports of commodity category i , and n is the number of the commodity categories considered.

According to the traditional explanation, the reallocation of resources from import-competing to export industries would improve productive efficiency and result in a redistribution of incomes from the former to the latter. Different conclusions are reached for the case of intraindustry specialization: the welfare effects of an increased exchange of consumer goods may now consist largely of improvements in the efficiency of exchange (the satisfaction of consumer wants) whereas specialization in narrower ranges of machinery and intermediate products will permit the exploitation of economies of scale through the lengthening of production runs. Correspondingly, in the absence of declining industries, the income redistributive effects of trade liberalization are expected to be smaller than in the traditional case.

It would further appear that the difficulties of adjustment to freer trade have been generally overestimated. It is apparent that the increased exchange of consumer goods is compatible with unchanged production in every country while changes in product composition can be accomplished relatively easily in the case of machine building, precision instruments, and various intermediate products. These considerations may explain why the fears expressed in various member countries of the Common Market concerning the demise of particular industries have not been realized. There are no examples of declining manufacturing industries in any of the member countries, nor have they experienced a wave of bankruptcies. Indeed, the number of bankruptcies has fallen since the Common Market's establishment, and there is little evidence of frictional unemployment.⁹

III

In the present note, I have attempted to derive certain conclusions regarding the effects of tariff reductions on trade among the industrial countries on the basis of information about changes in trade flows since the Common Market's establishment. The experience of the EEC is of particular interest in this regard, in part because—aside from Italy—these countries are on similar levels of industrial development, and in part because the relatively large reductions in duties within a short period of time make it possible to derive conclusions regarding the effects of trade liberalization on specialization. Although further research would be necessary to explore the experience of other countries, the findings of the paper support the hypothesis that trade among the industrial countries is characterized by intraindustry rather than interindustry specialization, and the results augur well for the consequences of multilateral tariff reductions in the Kennedy-round negotiations.

BELA BALASSA*

*According to national statistics on bankruptcies, after a temporary increase to 17,000 in the recession year 1958, the number of business failures in the countries of the EEC declined from slightly over 16,000 in 1956 and 1957 to 14,500 in the early sixties. At the same time, while data on frictional unemployment are not reported, it is questionable that this could have been substantial in a period when total unemployment in the Common Market fell by two-thirds.

The Weighted Average Marginal Tax Rate on Dividends Received by Individuals in the U.S.

The purpose of this study is to determine the weighted average marginal tax¹ rate on dividends received by individuals in the United States. The question to be answered is, to put it simply, "If U.S. corporations paid \$1 million more in dividends to individual stockholders, how much of this \$1 million would be paid to the Internal Revenue Service by these stockholders?"

This tax rate was desired for a number of reasons. First, it could be useful in the formulation of dividend policy by publicly-owned corporations. Second, it could measure the effect of personal taxation on the cost of retained earnings in cost-of-capital calculations.² Third, it could be useful in forecasting the macroeconomic effects of changes in total dividend payments. Fourth, it might be of interest to those formulating national income tax laws.

A second objective of this study is to determine the *trend* in the marginal tax rate. It was not clear to the author whether increasing dividends and increasing incomes would raise the weighted average, or whether these would be offset by a slowly increasing proportion of dividends being paid to stockholders in the lower tax brackets.

Third, during this study the United States Congress revised the tax laws, eliminating the 4 per cent dividend tax credit and reducing income tax rates,

¹Throughout this article "tax" refers to federal income tax. State income taxes are ignored.

²Some students of finance maintain that income tax paid on dividends is not pertinent to the determination of cost of capital.

so it was decided to estimate the effect of the new tax laws on the weighted average marginal tax rate on dividends received by individuals.

Results

The weighted average marginal tax rate on dividends included in individual tax returns was calculated to be:

<u>Year^a</u>	<u>Marginal Tax Rate</u>
1955	42%
1957	41%
1959	40%
1960	40%
1961	39%
1962	39%

Thus, under the 1954 tax code rates, the weighted average marginal tax rate on dividends received by individuals was approximately 39 per cent in 1962. The declining trend indicates that a slowly increasing proportion of dividends was being paid to stockholders in the lower tax brackets.

A separate calculation using the 1961 distribution of dividends with the new 1965 income tax rates, and eliminating the 4 per cent dividend tax credit, showed the expected weighted average marginal tax rate on dividends received by individuals for 1965 to be approximately 36 per cent. Although the marginal tax rate will rise by 4 per cent because of the elimination of the dividend tax credit, this will be more than offset by a reduction of about 8 per cent in the weighted average marginal tax rate by reason of reduced personal income tax rates. A continuation of the observed declining trend would further reduce the 1965 rate to approximately 35 per cent.

Prior Estimates by Other Researchers

The author is aware of only two other estimates of the weighted average marginal tax rate on dividends received by individuals. The first estimate was made by D. M. Holland: his figure for 1952 was 55.6 per cent [3, p. 120]. The second was made by G. Donaldson using data for 1959: his estimate was a weighted average tax "range" of from 52 per cent to 63 per cent [2, p. 128]. Details of how these two estimates were obtained are lacking, but it would appear that they were very rough and did not take into consideration differences in tax rates paid by different types of individual stockholders. The author feels, therefore, that the validity of the present results is much greater than the validity of these prior estimates. The author hastens to add that in the case of both of the other studies the calculation of marginal tax rate was incidental and not the focus of the study as is the case here.

^aThe last year for which the calculations were made was 1962 because the necessary data published by the Internal Revenue Service appear two to three years after the year in question.

Source of Data

The data used in the calculations were obtained from the *Statistics of Income: Individual Income Tax Returns* published for the years 1955-1962 by the U.S. Treasury Department, Internal Revenue Service. These published data are based upon stratified systematic samples consisting of 100 per cent of returns showing adjusted gross income of \$150,000 or more, and various lesser percentages of returns with adjusted gross income under \$150,000. The total size of these samples ranged from almost 250,000 returns (0.42 per cent of all returns filed) for the year 1955, to a total sample of 484,952 returns (0.77 per cent of the total number filed) for the year 1962.⁴

The data used understate dividends received by reason of the so-called "dividend gap," described by Holland as made up partly of dividends that did not have to be reported under the law, and partly of dividends that legally should have been reported but were not. Holland made different estimates of this gap using a variety of assumptions; in general it appears to be of the order of 10 per cent of total dividends received by individuals [3, Ch. 2]. One can only speculate as to the effect these dividends would have on the weighted average marginal tax rate, but it seems clear to the author that the direction of the change would be toward lowering the rate. This is because dividends legally unreported would have entered the calculation at a zero per cent marginal tax rate; the illegally undeclared dividends must have been distributed toward the lower income tax brackets by reason of the vigilance of the IRS in checking the tax returns of individuals in high income brackets.

Calculations

The general calculations used are illustrated in Table 1. The amounts of total dividends received by each category were obtained by rearrangement of the IRS data. The weighted average marginal tax rates for each of the first three categories were obtained by rather lengthy calculations, the details of which are available from the author. Basically these calculations involved the conversion of adjusted gross income classes to taxable income classes (with adjustments for capital gains income where appropriate), and the weighting of the marginal tax rate of each class by the dividends received by that class.

Use of Rate by Individual Corporations

The figure obtained for the marginal tax rate might not always be applicable directly to individual corporations for two reasons. First, not all stockholders are individuals; there are also corporate stockholders, nonprofit foundations, and others not taxed as individuals. Since a corporation can segregate the ownership of its stock by type of stockholder without much difficulty, however, and since the marginal tax rate of stockholders other than individuals can be estimated easily, the individual corporation could calculate the

⁴The relative sampling variability of these data can be obtained from the individual *Statistics of Income*. The author believes that their effect is insignificant in this study.

TABLE 1—GENERAL CALCULATIONS FOR 1962

Category	Total Dividends Received (millions)	Weighted Average Marginal Tax Rate for Category	
1. Joint returns with taxed dividend income	\$ 6,559	42.5%	2,788
2. "Single" returns with taxed dividend income	\$ 3,016	42.2%	1,273
3. Other returns* with taxed dividend income	\$ 676	44.8%	303
4. Nontaxable returns	\$ 780	0%	0
5. Taxable returns in which dividend income was completely covered by dividend exclusion	\$ 48	0%	0
	<hr/> \$11,079	<hr/>	<hr/> 4,364

$$\text{Over-all weighted average marginal tax rate} = \frac{4,364}{11,079} = 39.4 \text{ per cent}$$

* "Other returns" include separate returns of husbands and wives, heads of households, and surviving spouses.

weighted average marginal tax rate paid by *all* of its stockholders given this rate for its individual stockholders.

A more serious difficulty is that the composition of the particular corporation's individual-stockholder group may differ from the national average, making the national rate inapplicable. This is particularly true in closely-held corporations, but in this case it is often possible to obtain the marginal tax rates of the stockholders directly. In widely-held corporations, there is the possibility that to a certain degree investors in high tax brackets will avoid dividend-paying stocks and seek capital gains more actively. Some vague evidence of this was found by J. K. Butters, L. E. Thompson, and L. L. Bollinger in their 1949-1950 surveys of investment policies followed by individuals.

Except in very high income classes only a minority of individuals profess to have taken taxes into account in formulating their investment policies. Such shifts as have occurred appear to have been on the whole moderate in degree. Moreover, they have been opposite in direction, though the shifts toward more conservative investment holdings have substantially outnumbered those toward more venture-some holdings [1, pp. 178-79].

Butters, Thompson, and Bollinger, as might be expected, also found differences in investment objectives related to age, sex, and area (major metropolitan vs. nonmetropolitan areas). Obviously the composition of the stockholder group of an individual corporation can be expected to differ to some degree from the national average with regard to distribution among the various income tax brackets, but in the case of widely-held corporations this difference is not likely to be large.

Thus, the use of the 1965 rate determined in this study should enable many managements of individual corporations to estimate with reasonable accuracy

the weighted average marginal tax rate applicable to dividends paid to their own stockholders. This information is of use in dividend decisions and the calculation of cost of capital.

The Graduated Fair Return: A Regulatory Proposal

An examination of the regulated industries reveals a broad spectrum of rationales for government's deviation from the path of a *laissez faire* policy. One justification offered is that the industry is a "natural monopoly." A second rationale is the need to protect consumers in the sellers' markets of the services of public utilities. While these and other justifications for interference with the natural course of the market's operation are given, there still exists no precise line separating regulated from unregulated industries. Neither economists nor courts have drawn a strict line of demarcation. Despite this inability or unwillingness to delimit the two classes, the general goal of regulation is to improve the performance of the economy, in welfare terms, as compared with what it would be if the areas now regulated were uncontrolled.

It would seem, then, that public regulation should take a form that would enable the economy to come as close as possible to the achievement of a welfare optimum. Harvey Averch and Leland L. Johnson [1] have demonstrated, however, that the regulatory control most commonly used today, the "fair rate of return" criterion, induces a serious deviation from the optimal allocation of inputs. A welfare optimum would require that the marginal rate of substitution between any two factors equal the inverse of the ratio of their marginal costs [3, p. 140] [4, p. 41]. The fair rate of return does not lead to such an optimal state. Instead, it induces the firm subject to such regulatory control to use "noncapital" (call it labor) to a point where marginal revenue product equals marginal cost but to use capital at a level at which its marginal cost exceeds its marginal revenue product.

Nevertheless, regulatory commissions seem wedded to the notion of an equitable rate of return for the regulated industries. It seems logical that if we are to regulate by means of a fair-rate-of-return criterion, the input-allocation efficiency of regulation within this framework should be improved. To this end, this note proposes a regulatory scheme—the "graduated fair return" criterion—which remains within the framework of an equitable

return but which is more efficient in allocating inputs than is the present form of control.

The firm we are concerned with is a monopoly employing two inputs, capital (K) and labor (L) to produce a single homogeneous output (Y). The production function of the firm is assumed to be of the following form:

$$(1) \quad \begin{cases} Y = Y(K, L), & K \geq 0, \quad L \geq 0; \\ \frac{\partial Y}{\partial K} > 0, \quad \frac{\partial Y}{\partial L} > 0, & Y(0, L) = Y(K, 0) = 0. \end{cases}$$

The output of the firm is a function of the inputs of capital and labor, each of which has a positive marginal product. Positive quantities of both factors are required if any output is to result. The price (P) of the product is related to the output of the product by the inverse of the demand function. That is,

$$(2) \quad P = P(Y), \quad P'(Y) < 0.$$

We further assume that while the firm is a monopolist, it has no control over the price of its inputs. Hence, the costs of its inputs, r for capital and w for labor, are assumed fixed for all levels of purchase. Denoting profit by Π , we define it as

$$(3) \quad \Pi = PY - rK - wL.$$

It will be assumed that this profit function is concave.¹

For the sake of simplicity, without seriously diminishing the insights to be derived, let us assume that the value of depreciation of plant and equipment in the time period being considered and the cumulative value of depreciation are both zero.² In addition, we take the acquisition cost of a unit of capital to be unity. Hence, the value of the capital stock is equal to the physical quantity of capital (K). It should be noted that while we have posited that the acquisition cost of capital is unity, we have made no assumption beyond its constancy about the cost of capital, r , which is the interest cost involved in holding plant and equipment.

Having specified the model, it remains to define the efficiency in input allocation of a particular regulatory control. Under an optimal allocation of resources, with pure competition in buying factors, the marginal rate of substitution between any two factors will be equal to the inverse of the ratio of their prices. That is, in the present instance, the marginal rate of substitution of capital for labor ($\partial L / \partial K$) would equal the ratio of the cost of capital to the cost of labor (r/w). We shall define the efficiency (E) of a regulatory control as an input allocator to be the ratio

$$(4) \quad E = \frac{\partial L / \partial K}{r/w}.$$

¹ This enables us to limit our concern to the first-order conditions for profit maximization, since the second-order conditions will be fulfilled if the function to be maximized is concave.

² For a discussion of this assumption, see [1, p. 1054].

The efficiency of a particular control increases as E increases from zero to one, the latter being the point of maximum efficiency. Once E exceeds unity, the control is once again inefficient, its efficiency now decreasing as E increases.

The fair-rate-of-return criterion imposes the following constraint upon the regulated firm: after subtracting its operating costs from its gross revenue, the firm's net revenue should not exceed a given percentage (the fair rate of return) of the value ascribed to its property net of depreciation (the rate base). Since depreciation has been assumed away, the operating expenses of the firm in the present model are only labor costs, and the rate base is equal to the original value of the firm's capital stock. Moreover, with the cost of acquiring capital set at unity by assumption, the firm's rate base is equal to the physical quantity of capital it possesses. If we denote by s the fair rate of return determined by the regulatory agency, the regulatory constraint may be written as

$$(5) \quad \frac{PY - wL}{K} \leq s \quad \text{or}$$

$$(6) \quad PY - sK - wL \leq 0.$$

To determine the firm's optimal position when it operates subject to this regulation, Averch and Johnson make use of the Kuhn-Tucker conditions for a constrained maximum. These conditions are sufficient as well as necessary under our assumption of concavity of the profit function [2]. The firm attempts to maximize (3) subject to the constraint (6). The following Lagrangian function is formed:

$$(7) \quad \phi(K, L, \lambda) = PY - rK - wL - \lambda(PY - sK - wL).$$

As Averch and Johnson demonstrate [1, pp. 1055-56] the realm of interest is that in which $0 < \bar{\lambda} < 1$ where $[\bar{K}, \bar{L}, \bar{\lambda}]$ is the constrained maximum point. Under these conditions, the constraint is effective ($\bar{\lambda} > 0$) and the fair rate of return exceeds the market cost of capital ($\bar{\lambda} < 1$). Using the Kuhn-Tucker conditions, it can be shown [1, pp. 1055-56] that at the point of constrained maximization, with $\bar{L} > 0$,

$$(8) \quad w = \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial L}.$$

Labor is used up to the point where its marginal cost is equal to its marginal revenue product. At the same time, with $\bar{K} > 0$,

$$(9) \quad r - \bar{\lambda}s = (1 - \bar{\lambda}) \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K}.$$

We may, however, rewrite (9) as

$$(10) \quad r - \frac{\bar{\lambda}(s - r)}{1 - \bar{\lambda}} = \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K}.$$

Since $0 < \bar{\lambda} < 1$ and $s > r$, it is clear that

$$\frac{\bar{\lambda}}{1 - \bar{\lambda}} (s - r) > 0.$$

Consequently, capital is used up to a point at which its marginal cost exceeds its marginal value product,

$$(11) \quad r > \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K}.$$

The monopolistic firm maximizing profits subject to a fair-rate-of-return regulatory constraint uses labor efficiently, but it uses capital inefficiently.

The efficiency of this regulatory constraint can be found easily by dividing (10) by (8). We find

$$(12) \quad \frac{\partial L}{\partial K} = \frac{r}{w} - \frac{\bar{\lambda}}{1 - \bar{\lambda}} \left(\frac{s - r}{w} \right).$$

Since

$$\frac{\bar{\lambda}}{1 - \bar{\lambda}} (s - r) > 0$$

and since $w > 0$, we have

$$(13) \quad \frac{\partial L}{\partial K} < \frac{r}{w}.$$

By the definition of input efficiency, E , it is clear that $E < 1$ for the fair-rate-of-return constraint. It is, in fact, equal to

$$(14) \quad E = 1 - \frac{\bar{\lambda}}{1 - \bar{\lambda}} \left(\frac{s - r}{r} \right).$$

The inefficiency (*as an input allocator*) of the present fair-rate-of-return criterion derives from the constancy of the maximum allowable rate of return. The owners of the monopolistic firm considered could earn a net return of $s - r$ per cent on every unit of capital employed. The true marginal revenue product of capital may be, and most probably is, changing with the amount of capital and labor used. But the regulated firm's concern is not confined to relating this changing marginal revenue product to the marginal cost of capital when it determines the amount of capital to use. Instead, the firm must also weigh the constant net return of $s - r$ per cent it receives on the extra unit of capital for just bringing it into the production process. If the maximum allowable rate of return itself changed as capital was added, the effect of this inefficiency on the allocation of inputs could be diminished. This variable maximum allowable rate of return is the heart of the proposal made in this paper.

The fair rate of return available to a firm would change as the size of its capital stock changed. Either the equitable rate of return would be a decreasing function of the capital stock's size as soon as capital accumulation began or it would begin to decline only after the capital stock reached a certain threshold level. The essence of the proposal is that after some point the maximum allowable rate of return on capital would decline with increases in the amount of capital used. The fair return would, after some point, be graduated downward.

The graduated fair return could be implemented in one of two ways. The function relating the rate of return to the capital stock's size could be a continuous one or it could be a step function. In the first instance, after the fair return has begun its decline with further increments to the capital stock, each addition to that stock would call forth a new lower level of the equitable rate of return. On the other hand, the step-function relationship would involve the establishment of brackets of capital stock levels with declining rates applying to each bracket and with a constant rate applying within each bracket. For example, the firm might be allowed a maximum return of 8.0 per cent on the first \$100,000 of its capital stock, a maximum of 7.5 per cent on the next \$80,000, a maximum of 6.8 per cent on the next \$65,000, and so on. Obviously, in either case, the regulatory agencies which presently dictate the constant fair rate of return would be required to determine, after careful study by their research staffs, the functional relationship that should exist between the rate of return and the capital stock's size. This schedule, and I presume the step-function form would be the one adopted if either was employed, would undoubtedly vary from one regulated industry to the next.

To demonstrate that this graduated-fair-return criterion can, with a properly constructed function, constitute an improvement upon the present fair-rate-of-return method of control as an allocator of inputs, assume that the maximum allowable rate of return does begin to decline from the start. That is, for simplicity, suppose that the threshold level is zero. In order further to simplify the analysis, we posit the introduction of the first type of graduated-fair-return regulation, the continuously declining fair return. The constraint now imposed upon the monopolistic firm of the model is

$$(15) \quad \frac{PY - wL}{K} \leq s(K) \quad \text{or}$$

$$(16) \quad PY - Ks(K) - wL \leq 0,$$

where $s(K)$ is the continuous function relating the maximum allowable rate of return, s , to the size of the capital stock, K , and $s'(K) < 0$ for $K > 0$.

The monopolistic firm subject to the graduated-fair-return criterion maximizes its profit (3) subject to (16). The relevant Lagrangian expression is

$$(17) \quad \psi(K, L, \eta) = PY - rK - wL - \eta(PY - Ks(K) - wL).$$

The Kuhn-Tucker conditions for a maximum at the level of output given by K^0 , L^0 , η^0 are

$$(18) \quad (1 - \eta^0) \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K} - r + \eta^0 [s(K^0) + K^0 s'(K^0)] \leq 0, \quad K^0 \geq 0$$

$$(19) \quad (1 - \eta^0) \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial L} - (1 - \eta^0)w \leq 0, \quad L^0 \geq 0,$$

$$(20) \quad K^0 \left\{ (1 - \eta^0) \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K} - r + \eta^0 [s(K^0) + K^0 s'(K^0)] \right\} = 0,$$

$$(21) \quad L^0 \left\{ (1 - \eta^0) \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial L} - (1 - \eta^0)w \right\} = 0,$$

$$(22) \quad \eta^0 (PY - Ks(K) - wL) = 0, \quad \eta^0 \geq 0.$$

Our concern is with the case in which the regulatory constraint is effective that is, when $\eta^0 > 0$. If $\eta^0 = 0$, then the strict inequality can obtain in (16) so that $PY - wL < Ks(K)$. Since $\Pi = PY - rK - wL$, this means that $\Pi + rK < Ks(K)$ or $\Pi < [s(K) - r]K$. In short, when the constraint is ineffective, $\eta^0 = 0$ and the regulatory commission has designed its graduated-fair-return function so that at the firm's optimum $[s(K) - r]K$ exceeds the value of unconditionally maximized profit.

Turning to the case where the constraint is effective, (19) and (21) show that if any labor is used (which must be the case if any output is to be produced),

$$(23) \quad w = \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial L}.$$

Labor is employed up to the point where its marginal revenue product equals its marginal cost. The conditions of (18) and (20) indicate that with $K^0 > 0$,

$$(24) \quad r - \eta^0 [s(K^0) + K^0 s'(K^0)] = (1 - \eta^0) \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K}.$$

But this can be rewritten as

$$(25) \quad r - \frac{\eta^0}{1 - \eta^0} [s(K^0) + K^0 s'(K^0) - r] = \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K}.$$

The sum $s(K^0) + K^0 s'(K^0)$ is the value of the derivative of $Ks(K)$ with respect to K at the point of optimal output. It is the marginal return to the firm for the use of capital. Clearly, the schedule of equitable rates of return could be constructed so that at some point this marginal return is equal to the cost of capital, r . However, this involves removing entirely the decision concerning the quantity of capital to be used from the realm of the firm

and placing it, instead, completely with the firm's regulators. It is the case where $\eta^0 = 1$. Consequently we must confine our attention to the case where $\eta^0 < 1$ if we are intent upon examining the behavior of the firm subject to the constraint.

Attention is now centered upon the case in which $0 < \eta^0 < 1$, so that the constraint is effective and the marginal return on capital always exceeds the market cost of capital, allowing the firm to make its own decisions. Under these conditions, the second term on the left-hand side of (25),

$$(26) \quad \frac{\eta^0}{1 - \eta^0} [s(K^0) + K^0 s'(K^0) - r],$$

is positive. We find, as was the case with the constant-fair-rate-of-return control,

$$(27) \quad r > \left(P + Y \frac{dP}{dY} \right) \frac{\partial Y}{\partial K}.$$

Capital is used inefficiently, its marginal value product lying below its marginal cost. But it is used less inefficiently under a properly constructed graduated-fair-return criterion than under a constant one. The relevant comparison is the one in which the respective constraints are equally effective. This is the case in which the marginal value products of the two constraints (their dual prices) are equal. It occurs when the corresponding Kuhn-Tucker multipliers are equal, when $\bar{\lambda} = \eta^0$. Then, for equal fair rates of return, the graduated-return criterion is more efficient than the constant-return one. With $s = s(K^0)$, we find $s - r > s(K^0) + K^0 s'(K^0) - r$ since $s'(K^0)$ is negative by construction and K^0 is positive. Hence,

$$\frac{\bar{\lambda}}{1 - \bar{\lambda}} (s - r) > \frac{\eta^0}{1 - \eta^0} [s(K^0) + K^0 s'(K^0) - r].$$

A comparison of (10) and (25) now shows that r is closer to the marginal value product of capital under the graduated-return criterion.

The marginal rate of substitution between the factors under the graduated-return criterion is

$$(28) \quad \frac{\partial L}{\partial K} = \frac{r}{w} - \frac{\eta^0}{1 - \eta^0} \left(\frac{s(K^0) + K^0 s'(K^0) - r}{w} \right).$$

Dividing equation (28) by r/w , we find that the efficiency, as defined in (4), of the graduated-return method of control is

$$(29) \quad E = 1 - \frac{\eta^0}{1 - \eta^0} \left(\frac{s(K^0) + K^0 s'(K^0) - r}{r} \right).$$

This contrasts with the efficiency of the constant-fair-rate-of-return criterion given in (14). Once again, for $\bar{\lambda} = \eta^0$ and $s = s(K^0)$, which are the relevant conditions for a comparison, it can be seen that the negativity of $s'(K^0)$ ensures

that regulation under a graduated-fair-return scheme is more efficient as an allocator of inputs: E is closer to unity for the graduated criterion.

It is not asserted that the method of control proposed here is flawless. It requires careful planning by the staff economists of the many public utility commissions. It does not necessarily achieve an optimal allocation of inputs as judged by the relevant welfare criterion. In fact, we have seen that its efficiency is generally less than unity if input allocation is left within the realm of the firm's decision-making process. However, if it is desired to remain within the confines of a fair-rate-of-return regulatory program, it is incumbent upon us to look for alternative ways to control regulated industries so as to improve upon the inefficient criterion presently in use. The graduated-fair-return criterion is put forth here as such an alternative method of control.

Omissions in the Treatment of the Law of Variable Proportions

The purpose of this paper is to clarify two points with respect to the treatment of the Law of Variable Proportions (hereafter referred to as the Law) in most economics textbooks. The first concerns cost and product relationships in Stage III, commonly called the "irrational" region¹ of production, and the second deals with the symmetry of Regions I and III.

Although Stage III is an irrational area of production, it is not uncommon for firms lacking perfect knowledge actually to produce in that region, particularly in agriculture. As Bishop and Toussaint note [1, p. 41]:²

... evidence of production in Region III is often noted. For example, during the late summer and fall months, we frequently have evidence of too many cattle on a given quantity of pasture, resulting in overgrazing of pastures and less production than could have been obtained with fewer cattle. Also, we find evidence of overcrowding of broilers and layers in poultry houses.

¹ The terms "stage," "region," and "phase" are used interchangeably in this paper.

² For additional examples, see Heady [3, pp. 94 and 170].

regardless of the empirical incidence, however, the chief reason for examining cost curves in Stage III lies in presenting a complete and consistent treatment of the product-cost relationships in all three phases of the Law.

Most of the textbooks on economics discuss the various product functions and their interrelationships for all three phases of the production function in considerable detail. However, the corresponding cost functions are derived only for the first two phases of the Law and the relationship between product and cost functions in Stage III has been neglected, stated ambiguously, or misinterpreted.

The common practice is to draw a standard Sigmoid-type total cost function and its corresponding average and marginal cost functions. This tends to leave the reader either wondering as to the product-cost relationships in the third phase or under the erroneous impression that the total, average, and marginal cost functions as drawn are for all phases of the Law and that they continue to have a positive slope, even though the total product function assumes a negative slope in the third region.³ The writer has found both undergraduate and graduate students curious and confused about this.

The cost-product diagram (Figure 1) reproduced from a recent textbook on agricultural economics by Snodgrass and Wallace [6, p. 235] will show that the confusion is not confined to students alone. In providing a vivid illustration of the cost-product relationships, the authors completely overlook the point that the AVC function cannot continue to rise with a positive slope, as shown in Figure 1, for the output beyond point *C* on the TPP function or on the MPP function, because from *C* onwards the TPP is falling and the MPP is negative. It is true that the authors recognize "that the horizontal and vertical axes in each of the three figures [panels a, b, and c, in Figure 1] . . . are not comparable on a quantitative basis [but] the importance is to show the relationship between various points on the physical product curves and the cost curves . . ." [6, p. 235]. However, it is in this effort to show the relationship between various points on the product and cost functions that they either make the said error or at least fail to warn the reader anywhere in the book that such an error is due to the lack of exact quantitative correspondence between the horizontal and vertical axes of the three panels of the figure.

1. Interrelationships Between Product and Cost Functions

Figures 2 and 3 illustrate product-cost relationships for all phases of the Law. The product functions in Figure 2 are based on the production function:⁴

³ Heady's book [3, p. 94] is one of the few texts which advises the reader explicitly that the stages of increasing average and diminishing total returns are not drawn in subsequent chapters of the book. To the best of my knowledge, Vickrey [8, pp. 159-60] is the only author who makes a brief reference to and draws very tiny portions of the backward-rising AVC and TVC functions. However, he does not show the complete interrelationships between various product and cost functions.

⁴ This production function is taken from Heady's book [3, p. 39, n.1], except that the constant term, 40, has been dropped in order to keep our TPP function similar to the familiar textbook TPP which usually starts from the origin.

FIGURE 1. PRODUCT AND COST CURVES

$$(1) \quad Y = 4.0X + .5X^2 - .15X^3$$

where Y represents total physical product (TPP), and X stands for the variable input which is being applied to a fixed amount of another input. This fixed input (not explicitly included in the production function) is assumed to be perfectly divisible and adaptable. The marginal physical product (MPP) function, therefore, is given by

$$(2) \quad dY/dX = 4 + 1.0X - .45X^2.$$

In deriving cost functions (Figure 3) from product functions (Figure 2) it is assumed that the input market is perfectly competitive, so that the variable factor of production can be purchased at a constant price per unit

FIGURE 2. FACTOR-PRODUCT RELATIONSHIPS

of the input, irrespective of its quantity bought. The assumed input price, $P_x = \$3.00$ per unit.

From Figures 2 and 3 it will be noted that when Region III, the area of diminishing *total* returns, is included in the cost analysis, the various standard cost functions take on some peculiar attributes. In Figure 3, the total variable cost function (TVC) no longer remains single-valued; instead

it becomes bi-valued. The TVC for all phases of the Law is denoted by OAB ; the broken segment AB represents TVC for Stage III. Notice that in this region, TVC continues to rise until point B , a point representing a high positive cost but zero output, and has a negative slope because output is continuously falling, a phenomenon quite consistent with Stage III.

The average variable cost (AVC) function in Figure 3, represented by aDa' , develops a cusp at D , a point representing the end of Stage II and beginning of Stage III. After this point, the broken line Da' denotes AVC for Stage III. In this region, since output begins to fall after point D , Da'

FIGURE 3. COST-PRODUCT RELATIONSHIPS

assumes a negative slope. It is of the same general shape as the AVC function, aD , in Stages I and II, but is at a higher cost level.

Again, diminishing *total* returns in production cause a discontinuity in the marginal cost (MC) function. The complete MC function for all regions of the Law is shown by $mCA'C'm'$ (Figure 3), where mCA' represents the MC function for Stages I and II, and $C'm'$ denotes MC for Stage III. It will be noted from Figure 3 that at point A' (maximum output), the MC function attains a value of $\pm \infty$. Therefore after A' , the MC function for Stage III, $C'm'$, is (1) a discontinuous function at the maximum output level, and (2) is negative over the entire region (III) because the associated MPP function for this region in Figure 2 is negative.

In our traditional treatment of costs, we usually do not think in terms of negative costs. Negative MC is not to be construed to mean that for a certain rate of output the cost rate is negative (i.e., the entrepreneur is saving) but implies, instead, that after a certain point (A') if an effort is made to increase output, cost changes are positive even though output changes are negative, a phenomenon quite consistent with the input-output behavior, and the total cost-total product relationship in Stage III.

II. Symmetry of Regions I and III

This paper will conclude with clarification and elaboration of two final properties of the Law, viz., (1) interfactoral symmetry⁵ (or reversibility) in Regions I and III, and (2) the relationship, if any, between factor symmetry and product symmetry in Regions I and III. As early as 1936, Cassels in his celebrated article [2, p. 108] remarked: "The most important thing to observe about this law is that it is symmetrical and consequently the third phase is simply the converse of the first." Yet, most textbooks make scanty or no reference to this point.⁶ Furthermore, of the writers who do discuss the symmetrical nature of the Law, few, including Cassels, bring out the practical significance of the Law. Except for suggesting one operational aspect, namely, that total output can be increased in either Region I or Region III by reducing the relative intensity of the excessive factor, most of the writers leave the reader with the impression that symmetry of the Law is a mere theoretical nicety.

In our analysis of factor-product relations, Figure 2, it would be recalled that factor X (explicitly included in the production function) was treated as a variable factor of production. It was applied in equal incremental units to a given amount of some other factor (not explicitly included in the production function) which was treated as a fixed factor of production. Thus, in Region I, where the ratio of the variable factor to the fixed factor is relatively low, the marginal physical product for the variable factor is positive and greater than the average physical product (until $MPP_x = APP_x$

⁵The term "symmetry" is used here to imply reversibility of factor proportions (or factor position) rather than strict mathematical symmetry.

⁶Of some 15 texts consulted, only a few, viz., Heady [3, pp. 76-78], Leftwich [4, pp. 116-21], and Stigler [7, p. 125] discuss this point adequately. Even as good a text as Samuelson's [5, pp. 518-19] devotes only 5½ lines to this point.

at the outer boundary of Region I).⁷ In Region III, however, where the ratio of the variable factor to the fixed factor is relatively high, MPP of the variable factor is negative and below the APP of this factor.

By reversing the positions of these factors, one can easily see that a low variable-fixed factor ratio in Region I means a high fixed-variable factor ratio in the same region. Accordingly, when the MPP for our variable factor is positive in this region, it is negative for the other input in the same region. Likewise, in Region III a high variable-fixed factor ratio means a low fixed-variable factor ratio in the same region. Thus, when the MPP for our variable factor is negative, it is positive for the other factor. In short, Region I for one input is Region III for some other input, and vice versa.⁸

The importance of factor reversibility lies not only in deciding *when* a particular factor of production should be decreased to increase production but also in deciding *what* factor of production should be treated as variable or fixed in a given economic environment. These are not easy decisions. They confront not only entrepreneurs at the individual level but also policy makers at the national level whenever they are concerned with optimum resource allocation. An example from Heady [3, p. 77] will illustrate the point.

Within a cropping year, a farmer may consider hog numbers as fixed and corn as variable; he can either sell the year's corn crop or feed it in varying amounts to a given number of spring-farrowed pigs. Or, he can consider the corn crop as fixed and vary the number of hogs in proportion to it; the corn can be stored into the next year and opportunities will be open for farrowing more pigs. At the national level, food emergencies may arise which call for either feeding more or less grain to a given number of hogs within a year or storing the corn and increasing the number of hogs to which it might be fed. Which system will give greatest profits to the farmer or food to the nation?

Answers to such complicated problems can be determined only by an analysis of both the physical and economic relationships. The important point is that reversibility of the technical inputs not only allows the interchange of factor positions but also provides the necessary, though not sufficient, basis on which this choice is exercised. The usual textbook discussion of symmetry and optimum factor proportions then becomes meaningful.

The second point concerns the relationship, if any, between factor symmetry and product symmetry in Regions I and III. Having read the class assignment on the symmetry of the Law in standard sources, many students ask: If Regions I and III are symmetrical, why doesn't the TPP curve in Region III have an inflection point corresponding to the inflection point in Region I? In terms of the MPP function, why doesn't it achieve a maxi

⁷ It is recognized that the location of the boundary between Regions I and II at the point where $MPP = APP$ holds true only when the production function is homogeneous of the first degree. If either diminishing or increasing returns to scale are present, the boundary between Regions I and II will not be marked by the equality of MPP and APP.

⁸ For an excellent graphic and tabular illustration of this point, see Leftwich [4, pp 116-21].

imum negative value in Region III corresponding to the maximum positive value in Region I, and reverse its direction toward zero (B , Figure 2) as it does toward the zero value (A' Figure 2)?

These questions reveal a confusion between factor symmetry and product symmetry in Regions I and III. Even though factor symmetry makes Regions I and III the converse of each other, it does not necessarily mean that

FIGURE 4. FACTOR-PRODUCT RELATIONSHIPS

the *rate* of increase in total product in Region I must be symmetrical to the *rate* of product loss in Region III. Hence the difference in the exact behavior and shapes of the TPP and MPP curves in Regions I and III.

The MPP curve in Region III would achieve a maximum negative value and reverse its direction to join *B* only if the TPP curve in Region III, un-

FIGURE 5. COST-PRODUCT RELATIONSHIPS

der some special circumstances, were exactly symmetrical (used here in the mathematical sense) to the TPP curve in *both* Regions I and II, i.e., if the TPP were symmetrical about the input value corresponding to the maximum TPP value. This is illustrated in Figure 4 where the TPP is symmetrical about input (X) value of 13. The MPP in Region III, therefore, is an exact mirror image of the MPP in Regions I and II. The corresponding cost functions are shown in Figure 5. Here the MC function in Region III, corresponding to the MPP behavior, is also an exact mirror image of the MC function in the first two regions. But, this situation, as remarked earlier, is rather unusual. Theoretically, there is more reason to believe that the TPP curve would be nonsymmetrical than symmetrical. As Cassels stated [2, p. 109, n. 10], "since the *proportions* of the factors are less affected by each additional unit of the variable factor as we move to the right along the X -axis it is clear that *in general* the third phase must be more prolonged than the first."

Interindustry Wage Change Dispersion and the "Spillover" Hypothesis

Since the advent of unionism as a quantitatively important economic force, the economics literature has been replete with references to the quantitative relevance of equitable or coercive comparisons in the wage determination process. The terminology used to describe this process has varied

considerably—spillover, key bargains, wage leadership, pattern wage adjustment, imitation, and diffusion. The basic notion underlying what may generally be called the “spillover” hypothesis is that wage movements in the i th sector not only reflect traditional market forces in that sector but also reflect wage movements in some j th sector.¹ The wage relationship between the i th and j th sectors is “derived” from a political influence theory which suggests that traditional economic variables are to be supplemented, or in some cases supplanted, by additional spillover variables if a complete explanation of wage movements is to be obtained. The theory is sometimes restricted to wage determination under collective bargaining, but it is also applied to cases where monopsonistic employers administer wages and seek simple decision rules.

The interindustry dispersion of wage changes computed over different time periods, for groups of industries alleged to be part of a common spillover domain, is commonly cited as evidence to support this model. From these data it is argued that the dispersion is either absolutely “small,” a fact allegedly consistent with the spillover hypothesis, or smaller than the dispersion in some other sector or in some earlier time period in which spillovers were inoperative.² The purpose of this paper is to comment on the theoretical and statistical appropriateness of this procedure. The following questions will be considered: (1) Does the spillover hypothesis imply that the interindustry dispersion of wage changes within a spillover domain will be absolutely small in some sense? (2) Does it imply that the dispersion will be smaller than that which would be generated by market forces alone? (3) Is the test statistically appropriate?

I. *Market Wage Determination and Wage Change Dispersion*

The implications of the traditional market hypothesis for interindustry wage change dispersion will first be examined, and then compared with those of a spillover model of wage determination. The market theory of the wage determination process asserts that, for a particular industry, wage changes will reflect variation in underlying labor demand and supply conditions. According to traditional economic theory, the demand by the i th industry for any factor of production, including labor, is a function of the prices of all other inputs, technology, and the relevant variables of the product-demand schedule. The supply of labor to the i th industry is a function of the wage rate in that industry and the alternative wage rates for labor of comparable skill offered by other industries. Adding the equilibrium condition that labor supplied equals labor demanded, a reduced-form expression relating the equilibrium wage rate and the exogenous de-

¹ The term wages can mean many things—straight time hourly earnings, average hourly earnings, average hourly earnings plus fringe benefits, etc. And wage changes may be computed in percentage, absolute, or, for that matter, any units. Although the term “wage changes” will be interpreted to mean percentage changes in average hourly earnings, the arguments in this paper are independent of this choice.

² The formal and informal use of this kind of evidence is found in many studies as well as in some labor economics textbooks. See, for example, [1, pp. 386–92] [4] [5] [7, pp. 193–94] [8.]

mand and supply variables can be obtained. In the neighborhood of equilibrium this expression can be approximated as

$$(1) \quad \dot{W}_i^* = B_0 + B_1 \dot{X}_i + B_2 \dot{W}_i^A + u_i,$$

where \dot{W}_i^* is the equilibrium percentage change in the wage rate paid by the i th industry; \dot{X}_i is the percentage change in a labor demand shift variable;³ \dot{W}_i^A is the percentage change in alternative wages for labor of skill comparable to that used in the i th industry; and u_i is a random-error term summarizing omitted factors and random disturbances in the structural equations. This equation gives the percentage change in wages for the i th industry as a function of the percentage change in the relevant demand and supply shift variables.

Given a sample of n industries for which the percentage change in wages is computed over a particular time period, the sample variance of wage changes is defined as

$$(2) \quad S_{\dot{W}^*}^2 = \frac{\sum_{i=1}^n (\dot{W}_i^* - \bar{\dot{W}})^2}{n - 1},$$

where $\bar{\dot{W}}$ is the mean of the \dot{W}_i^* 's.⁴

If the explanatory variables are uncorrelated with the error term, the sample variance of \dot{W}^* is given by the formula,

$$(3) \quad S_{\dot{W}^*}^2 = B_1^2 S_{\dot{X}}^2 + 2B_1 B_2 S_{\dot{X}\dot{W}^A} + B_2^2 S_{\dot{W}^A}^2 + S_u^2,$$

where $S_{\dot{X}\dot{W}^A}$ is a covariance, while all other S^2 terms are variances.

The sample variance of \dot{W}^* will depend on the variance of the error term (S_u^2) and the sample variance of the explanatory variables. If the sample of industries chosen is such that each industry exhibits similar changes in demand and supply conditions, the only source of variance in the sample will be the variance of the error term, which may be either "large" or "small." On the other hand, if the industries diverge widely in their demand and supply change characteristics, this divergence will be an additional source of variation in the sample \dot{W}^* 's. In any event, the theory does not specify that S_u^2 will be small, and there is no basis for forming an a priori expectation concerning the sample variance (2). In short, while the market theory of wages names the relevant explanatory variables and specifies the signs of the structural coefficients, it implies nothing about the variance of interindustry wage changes.

³ It is assumed that the demand and supply shift variables can be summarized by the variables X_i and W_i^A , but the argument is unaffected if these variables and their coefficients, B_1 and B_2 , are interpreted as vectors.

⁴ In equation (2) and elsewhere throughout this paper, sample means and variances are computed as unweighted averages rather than as weighted averages. Since this simplification does not affect any results qualitatively, it was adopted to eliminate notational complexity which would only obscure the main points we are making.

⁵ See, for example, P. Hoel [3, p. 231].

II. *The Competitive Hypothesis: A Special Case of the Market Hypothesis*

If the change in wage rates is computed over a sufficiently long period of time, the competitive hypothesis asserts that the supply of labor to the i th industry will be infinitely elastic.⁶ Under these conditions, changes in the demand for labor will affect employment but not wages. Wages will change only in response to changes in the supply price of labor, which will depend on changes in alternative wages available for factors of skill comparable to those employed in the i th industry. Mathematically,

$$(4) \quad \dot{W}_i^* = \dot{W}_i^A + \epsilon_i.$$

In the special case in which all industries in the sample use comparable skill mixes during the entire period, the sample variance of \dot{W}^* is simply equal to the sample variance of ϵ , which may be large or small. However, if the sample includes industries which are not all comparable in this respect, the general expression is again given by

$$(5) \quad S_{\dot{W}^*}^2 = S_{\dot{W}^A}^2 + S_{\epsilon}^2.$$

In this more general case, the sample variance of $S_{\dot{W}^*}^2$ is equal to the sample variance of the random-error term (S_{ϵ}^2) plus the sample variance of the alternative wage changes ($S_{\dot{W}^A}^2$). Even under the special assumption of the competitive hypothesis, the sample variance of wage changes may be large or small.

III. *The Spillover Hypothesis and Wage Change Variance*

One version of the spillover hypothesis emphasizes the influence of wage outcomes, in a theoretically specified sector of the economy, on the bargaining outcome in a particular industry, but not to the complete exclusion of industry specific supply and demand factors; institutional relationships among industries supplement rather than supplant a market theory of wage determination.⁷ The hypothesis may be expressed in the form of two equations. Let the unobserved market-determined percentage wage change in the i th industry be given by

$$(1) \quad \dot{W}_i^* = B_0 + B_1 \dot{X}_i + B_2 \dot{W}_i^A + u_i.$$

An equation describing the impact of spillovers is added to obtain a full description of the wage determination process. The spillover may be introduced as follows:

$$(6) \quad \dot{W}_i = \dot{W}_i^* + \delta(\dot{W}_i^* - \dot{W}_i^*) + v_i,$$

⁶ M. Reder [6, pp. 299-311] gives an excellent summary of the competitive theory in which this interpretation and its empirical implications are developed extensively.

⁷ A model with these features has been used recently by O. Eckstein and T. Wilson [2].

where \dot{W}_i is the observed percentage change in wages; \dot{W}_i^* is the percentage wage change in some other sector of the economy which influences the bargaining demands of unions in i as well as the offers of employers in i ; v_i is a random-error term summarizing omitted variables which influence the bargaining outcome in the i th industry;⁸ and δ is a spillover coefficient. Equation (6) may be rewritten as

$$(7) \quad \dot{W}_i = (1 - \delta)\dot{W}_i^* + \delta\dot{W}_i^* + v_i.$$

This relationship summarizes the influence of both market and institutional forces on the determination of wages in the i th industry. If $\delta=1$, then industry specific market forces play no role in wage determination and wages are determined only by wage outcomes in the spillover sector and by random factors as summarized by v_i .

Now consider a sample of wage changes for a group of industries, all of which are members of the same spillover domain, which implies that \dot{W}_i^* is the same for all i . If the above model is correct, the sample interindustry variance of wage changes will be given by

$$(8) \quad S_{\dot{W}}^2 = (1 - \delta)^2 S_{\dot{W}^*}^2 + S_v^2.^9$$

In an absolute sense, there is no a priori reason for assuming that the variance in (8) will be small, for even if it is maintained that δ is near unity, the error term v may generate considerable interindustry wage change variance. As stated, the theory specifies (1) the relevant spillover domain, which is institutionally defined, and (2) the signs of the coefficients. The additional assumption that σ_v^2 is small or zero is arbitrary, and has no basis in economic or statistical theory.

Furthermore, the theory does not imply that the variance of wage changes will be smaller in the presence of spillovers (8) than in their absence [i.e., in (3)]. From (8) we see that the spillover and market models would imply the same variance in the observed percentage change in wages if

$$(1 - \delta)^2 S_{\dot{W}^*}^2 + S_v^2 = S_{\dot{W}^*}^2,$$

that is, if

$$S_v^2 = [1 - (1 - \delta)^2] S_{\dot{W}^*}^2.$$

⁸ The error term v has the same underlying rationale as the error term in (1). Equation (6) is a behavioral relationship which in the unionized case summarizes the collective bargaining process. Underlying this relationship is a set of behavioral relationships describing the employer's and union's bargaining policies. Obviously, the variables included in (6) do not exhaust the many forces which influence both parties. The union's bargaining policy, for example, may be influenced by leader-member relationships, the age of workers (which influences their taste for money wages versus fringes), and a host of other forces.

⁹ Because it is assumed that the sample consists of industries in the same spillover domain, the variance term $S_{\dot{W}^*}^2$ is zero. For expository simplicity, we assume that \dot{W}^* and v are uncorrelated.

The market model would imply greater variance of wage changes than the spillover model if

$$S_v^2 < [1 - (1 - \delta)^2] S_{w*}^2,$$

while the spillover model would yield the greater variance if the inequality were reversed.

Apparently a combined spillover-market mechanism of wage determination does not necessarily imply a lower variance of wage changes than a pure market mechanism, and the comparison of wage change variances for two sectors, one with spillovers and one without them, is an ambiguous test procedure. This proposition holds even if S_{w*}^2 is statistically controlled. However, given identical or randomized values of S_{w*}^2 and S_v^2 , wage change dispersion, in the context of a spillover model, varies systematically with δ . Provided that industry groups can be ranked according to the size of δ , meaningful variance comparisons are empirically feasible, at least in principle, although none of the existing literature has demonstrated that the necessary assumptions are satisfied.¹⁰

The difficulties of the variance comparison test are not easily avoided by other test procedures. The principal weakness of the spillover theory is its inability to specify unambiguously the spillover domain. The counterpart of this difficulty in the market model is the specification of the alternative wage domain. It is not unlikely that these two domains will overlap, creating a serious identification problem. For example, a positive time-series relationship between wage changes in one sector and those in a spillover sector will be ambiguous evidence of a spillover mechanism unless one can specify a spillover variable not easily interpreted as a labor supply variable. This problem is particularly acute if one works with broadly defined sectors.

IV. Statistical Considerations

Comparisons of variances of wage changes have been shown to be of questionable value as a means of discriminating between a market model and a spillover model of wage changes, since there is no basis for forming a priori expectations of the values of the residual variances of these models. It will now be shown that even if the absolute or relative values of these variances were known for a given level of aggregation, it would still be impossible to make inferences from a comparison of wage change variances since (1) within each set of industries the variance of wage changes is a decreasing function of the level of aggregation, and (2) it is generally not clear when data for two or more industries represent the same level of aggregation.

The absolute value of interindustry wage change variance will be sensitive to the observation unit chosen. The variance may be computed on an

¹⁰ The expectation that the wage change variance declines as δ rises requires the maintained hypothesis that $\delta \leq 1$; otherwise, from (8) we see that S_{w*}^2 is not a monotonically decreasing function of δ .

establishment basis or on the basis of a collection of establishments corresponding to a particular aggregation procedure. In general, a smaller interindustry variance will be observed if the observation unit is defined in terms of, say, the 2-digit industrial classification than if it were defined by, say, the 3-digit classification. Measures of dispersion vary systematically with the aggregation level because aggregation averages out, so to speak, random errors.¹¹ In terms of the interindustry variance of wage changes, this relationship between aggregation and dispersion is verified by the available data, which indicate that the aggregation effect is quantitatively important.

Percentage changes in average hourly earnings over the period 1958-63 were computed for three industry groups—durable manufacturing, nondurable manufacturing, and nonmanufacturing, which includes trade, transportation, services, etc. The interindustry variance is computed for each industry group at the 2-, 3-, and 4-digit level whenever sufficient data are available.¹² The standard deviation for each of the three sectors at each of the three levels of aggregation is shown in Table 1. Also shown in the table are the arithmetic mean of wage changes, the coefficient of variation (the standard deviation divided by the mean times 100), and the range.

The statistics in Table 1 highlight the main argument of this section. For each of the three sectors—durables, nondurables, and nonmanufacturing—both the standard deviation and the coefficient of variation, a measure of relative dispersion, decline in magnitude as the level of aggregation increases. In the durable-goods sector, for example, the standard deviation is about 50 per cent larger when computed on the basis of a 4-digit industry classification than when computed at the 2-digit level. The absolute size of the variance is a statistical artifact and the notion of an absolutely small dispersion is either meaningless or not very helpful.

The data in Table 1 also reveal an inherent difficulty in testing the spillover hypothesis by comparing interindustry variance between two sectors, one in which spillovers are alleged to operate and one in which they do not. It is suggested frequently that the extensively unionized durable-goods sector is a spillover domain. Assuming that spillovers reduce variance, which coefficients of variation (or other measures of dispersion) are to be compared? It is not at all obvious that wage dispersion at the 2-digit level in the durable sector should be compared to its counterpart in the nondurable or nonmanufacturing sector. It may be no less appropriate to compare 2-digit durables with, say, 3- or 4-digit nondurables than with 2-digit nondurables. The Standard Industrial Classification at the 2-digit level, or at

¹¹ For example, with some modest manipulation we can obtain from the well-known formula for partitioning a sum of squared deviations the relationship, $S_{3,g}^2 = S_{3,2}^2 + S_{3,g}^2$, where $S_{3,g}^2$ is the variance of 3-digit wage changes computed around the global mean of wage changes; $S_{3,2}^2$ is the variance of 3-digit wage changes computed around the respective 2-digit means; and $S_{2,g}^2$ is the 2-digit variance computed around the global mean. In general, $S_{3,2}^2 \neq 0$ and, consequently, $S_{3,g}^2 > S_{2,g}^2$.

¹² Because A. M. Ross [7] and others assert that the durable sector is a single spillover domain, this sector has been isolated in computing the variances. The other two groupings were arbitrarily chosen.

TABLE 1—MEASURES OF ABSOLUTE AND RELATIVE DISPERSION FOR PERCENTAGE CHANGES OF AVERAGE HOURLY EARNINGS FOR 2-, 3-, AND 4-DIGIT SIC CLASSIFICATIONS, 1958-63*

Industry Group	Level of Aggregation		
	4-Digit	3-Digit	2-Digit
<i>Manufacturing</i>			
Durables:			
<i>S</i> (Standard deviation)	3.06	2.62	2.04

any level, does not necessarily imply the same level of aggregation for all industries.¹³ Unless comparability is specified, any conclusion may be reached by making the appropriate arbitrary comparison.¹⁴

V. Conclusions

Three major conclusions follow from the analysis in this paper: (1) the absolute dispersion of wage changes is a statistical artifact; (2) in comparing two different sets of industries, the level of aggregation affects the amount of measured dispersion, yet comparability is difficult to obtain or even

¹³ For example, does the 4-digit industry "Farm Machinery and Equipment" (SIC-3522) represent the same level of aggregation as the 4-digit industry "Motor Vehicles and Parts" (SIC-3717), or the 3-digit industry "Motor Vehicles and Motor Vehicle Equipment" (SIC-371), or the 2-digit industry "Transportation Equipment" (SIC-37)?

¹⁴ This problem arises even when the dispersion for a group of 2-digit industries is examined at different points in time to determine whether the advent of unionism has reduced inter-industry wage change dispersion. This technique has been employed by J. E. Maher [5] who finds that coefficients of variation in manufacturing have risen rather than declined since the growth of unionism in the 1930's. While this would appear to contradict the spillover hypothesis, the aggregation issue makes it difficult to interpret this evidence.

specify; (3) for the same set of industries, spillovers need not imply a smaller dispersion than market forces.

Returns to Scale and the Spacing of Isoquants

In the usual statement of production theory, average returns to scale are specified in terms of scale elasticity: $E = (dQ/Q)/(dk/k)$, where $Q = q(k\bar{X}, k\bar{Y})$, $k > 0$, and \bar{X} and \bar{Y} are initial values of X and Y which fix factor proportions when k , the scale coefficient, equals 1.¹ Further, in the usual statement of production theory, the scale elasticity is related to the spacing of isoquants as follows: When $E > 1$, the successively numbered isoquants are getting ever closer (which means that the production surface, viewed from the origin, is getting steeper and steeper; i.e., $q_k'' > 0$). When $E < 1$, the isoquants are getting ever farther apart ($q_k'' < 0$); and when $E = 1$, it is asserted that the isoquant spacing does not change ($q_k'' = 0$). It is the pur-

¹ The only exception that we have been able to find in a check of the literature appears in Schneider [1, p. 149]. Professor Schneider defines constant, increasing, and decreasing returns to scale as follows:

$dx/d\lambda$ is constant

$dx/d\lambda$ increases as λ increases

$dx/d\lambda$ diminishes as λ increases

where x represents output and λ represents the scale coefficient (our k).

pose of this note to show (1) that isoquant spacing depends on marginal, not average, returns to scale; and (2) that the above usually-stated relationships between average returns to scale and spacing of isoquants are accurate only for homogeneous production functions.

Scale elasticity is the ratio of marginal returns to scale to average returns to scale: $E = q'_k / (Q/k)$. In the case of a linear homogeneous production function, q'_k and Q/k are both constant and equal and $E = 1$. And since q'_k is a constant, the isoquants are equally spaced. For homogeneous functions, where there are constantly increasing average returns to scale, marginal returns to scale must always be greater than average returns to scale and also constantly increasing, E is a constant greater than 1, and the isoquants are spaced closer and closer together. For homogeneous functions where average returns to scale are constantly decreasing, $E < 1$ and the isoquants are spaced farther and farther apart.

Figures 1a and 1b show that these relationships do not necessarily hold for nonhomogeneous functions. These figures show increasing average returns to scale for values of k up to k_2 and decreasing average returns beyond k_2 . (This is the usual assumption of economic theory.) Marginal returns are increasing up to the inflection point, k_1 , and decreasing thereafter. Thus, while average returns to scale are increasing up to k_2 , marginal returns to scale first increase, reach a maximum, and then decrease, but they are always greater than average returns. In terms of isoquants, this would mean that up to k_1 the isoquants are getting ever closer and beyond k_1 ever farther apart. But since the marginal returns are greater than the average returns, $E > 1$ up to k_2 . These diagrams have thus shown that the usually posited relationships between average returns to scale (and E) and spacing of isoquants are violated in the case of a nonhomogeneous production function.

We now show the *general* relationship between scale elasticity and the spacing of isoquants along a ray from the origin. We begin with the definition of scale elasticity:

$$(1) \quad E = \frac{q'_k}{\frac{Q}{k}}.$$

Differentiating with respect to k :

$$\frac{dE}{dk} = \frac{d}{dk} \left[q'_k \frac{k}{Q} \right] = q''_k \frac{k}{Q} + \frac{1}{Q} q'_k - \frac{k}{Q^2} [q'_k]^2.$$

Substituting (1) in the above, we have:

$$(2) \quad \frac{dE}{dk} = q''_k \frac{k}{Q} + \frac{1}{Q} q'_k (1 - E).$$

Figure 1a

Figure 1b

For homogeneous functions, E is a constant, and therefore, $dE/dk=0$.² In addition we assume $k>0^3$ and $q'_k>0$. It follows from (2) that:

$$q''_k \frac{k}{Q} = -\frac{1}{Q} q'_k (1-E)$$

and

$$(3) \quad \frac{q''_k}{q'_k} = \frac{E-1}{k}.$$

Thus, when $E>1$, $q''_k>0$ (isoquants are ever closer)
 when $E=1$, $q''_k=0$ (isoquants are equally spaced)
 when $E<1$, $q''_k<0$ (isoquants are ever farther apart).

The spacing of isoquants is not discussed at length in the literature; where it is discussed, it is implicitly or explicitly in terms of homogeneous production functions. For nonhomogeneous functions, we investigate first the case where scale elasticity is positive and increasing, i.e., $dE/dk>0$. Again we assume $k>0$ and $q'_k>0$. From (2):

$$\frac{dE}{dk} = q''_k \frac{k}{Q} + \frac{1}{Q} q'_k (1-E) > 0$$

and

$$(4) \quad \frac{q''_k}{q'_k} > \frac{E-1}{k}.$$

If $E>1$, $q''_k>0$
 $E=1$, $q''_k>0$
 $E<1$, $q''_k \geq 0$.

$$^2 q(k\bar{X}, k\bar{Y}) = k^i q(\bar{X}, \bar{Y})$$

$$q'_k = ik^{i-1} q(\bar{X}, \bar{Y})$$

$$\frac{Q}{k} = \frac{k^i q(\bar{X}, \bar{Y})}{k} = k^{i-1} q(\bar{X}, \bar{Y})$$

$$E = \frac{q'_k}{\frac{Q}{k}} = \frac{ik^{i-1} q(\bar{X}, \bar{Y})}{k^{i-1} q(\bar{X}, \bar{Y})} = i \text{ (a constant)}$$

$$\frac{dE}{dk} = \frac{d}{dk} (i) = 0.$$

³ In Figures 1a and 1b we show $k=0$ at the origin. This is the case where no output is being produced. For algebraic exposition, it is convenient to neglect the trivial case where no output is being produced; i.e., $k=0$.

Of more importance for economic analysis is $dE/dk < 0$, i.e., a stage of increasing returns to scale followed by constant and/or decreasing returns to scale. Our assumptions are now $dE/dk < 0$, $k > 0$, and $q'_k > 0$. Then (2) gives:

$$\frac{dE}{dk} = q''_k \frac{k}{Q} + \frac{1}{Q} q'_k (1 - E) < 0$$

$$(5) \quad \frac{q''_k}{q'_k} < \frac{E - 1}{k}.$$

If $E > 1$, $q''_k \geq 0$
 $E = 1$, $q''_k < 0$
 $E < 1$, $q''_k < 0$.

Referring to Figure 1b, we see that, with the usual assumption of an initial stage of increasing returns to scale followed by a stage of constant average returns to scale and then a stage of decreasing average returns to scale, $E > 1$ in the first range, $E = 1$ in the second range, and $E < 1$ in the third range. We have shown, however, that marginal returns to scale may be increasing, constant, and decreasing when average returns are increasing; but marginal returns must be decreasing at the point of diminishing average returns to scale and thereafter. Thus, the most general production function diagram would show isoquants along a ray from the origin initially ever closer, then equally spaced, and finally ever farther apart within the range of increasing average returns (up to k_2 in Figure 1b) and continuingly ever farther apart in the stage of decreasing average returns.

Lasting Effects of Economics Courses at Different Types of Institutions

We recently reported the results of a nationwide study of the economic understanding of a large sample of all high school social studies teachers in the United States [1]. These results indicated, somewhat alarmingly, that teachers who had taken one or two semesters of elementary economics in college did not do significantly better on a widely used "Test of Economic Understand-

ing" than did those who had taken no college economics, and that not until the teachers had taken five or more college economics courses did they perform significantly better on the test than those who had had no economics.

Different hypotheses have been advanced to explain this result. One is that high school social studies teachers retain little from their college economics courses because they have taken relatively weak courses at relatively weak colleges. This note presents evidence on how much lasting learning in economics occurred at institutions of five different types, evidence which suggests that the lasting results were greatest at small liberal arts colleges and least at large universities, with intermediate results at other types of institutions. The results also provide separate data on students in "education" majors and in other undergraduate fields.

The results reported here are based on the same nationwide survey reported in the earlier article, which included information on where each teacher took his college economics; they are thus subject to the same reservations as those reported in the earlier article. We present them because we believe they may be of interest to the profession, not because we believe they represent a complete measure of the achievements of economics courses at different institutions, for they are obviously only a very partial measure.

I

To investigate the possibility that the discouragingly low retention of economics results primarily from students having taken their courses at relatively weak institutions or in relatively weak courses for particular groups of students, we first classified all colleges and universities represented in the sample into five groups: (1) 20 "high prestige" schools, including both universities and liberal arts colleges;¹ (2) 50 large universities, excluding those included in group (1); (3) 50 well-known liberal arts colleges, excluding those in group (1) above; (4) "teachers colleges," whether or not they still use that title in their official names; and (5) all other schools. Since the basic survey focused on teachers, it was reasonable to suppose that a large number of them would have been "education" majors, and other studies have indicated that such majors are relatively weaker students than other majors. We therefore classified separately education majors and noneducation majors in each group of schools.

Table 1 summarizes the raw test performances of students from the five different types of schools, without holding constant differences in student ability, number of courses taken, and the like; a regression analysis aimed at isolating these variables within the different groups of schools is reported in Table 2. The first three columns of Table 1 report the basic scores for students with

¹ The group includes six leading private universities, two state universities, and two institutes of technology from the larger schools; and three coeducational, three men's, and four women's smaller liberal arts colleges. The selection was based on general academic standing, and on average CEEB scores for entering students.

A separate analysis was also made dividing the ten liberal arts colleges from the ten universities within this group, but it seemed desirable to investigate separately the results at the entire group of such "prestige" schools with especially high prestige faculty members and students of especially high academic ability.

no economics and those taking some college economics in each class of school, and the difference between the no-economics and with-economics scores for each class. In each type of school there was some improvement from taking economics courses, but the degree of improvement ranged from virtually none for the large state universities to nearly six points on a 50-point scale for the 50 leading liberal arts colleges, as shown in column 3. If we assume (not implausibly) that *within* each of the five groups of schools students who do and do not take economics are otherwise similar (except for the education-noneducation breakdown shown), then the improvements shown in column 3 should provide some indication of the lasting effect produced on students at the various schools. It will be recalled from the earlier article that on the

TABLE 1—TEST SCORES OF STUDENTS WITH AND WITHOUT COLLEGE ECONOMICS*

Type of School	All Students			Noneducation Majors			Education Majors

Other Schools	30.7	34.5	+3.8*	31.9	35.7	+3.8*	29.9	33.2	+3.3*
All Schools	31.6	34.7	+3.1*	33.2	36.6	+3.4*	30.8	33.7	+2.9*

* For information on test used and on schools included in various categories, see text. Number of students in each category shown in footnote to Table 2.

* Statistically significant at the .05 level. Negative figure for education majors at "prestige" schools rests on only six students in the no-economics category; most of the "high prestige" schools do not offer, or emphasize, undergraduate majors in "education."

average the teachers in the survey had been out of college about eight years.

The next six columns of Table 1 show the same data separately for noneducation and education majors. While noneducation majors show a consistently higher *level* of achievement, the general pattern of *improvement* appears to be similar for education and noneducation majors.²

The basic data in Table 1 may, however, conceal a variety of factors which help to explain the results. For example, on the average, students in some types of institutions may have taken more courses in college economics than those at others; particularly high-ability students may have chosen economics in some colleges, and relatively low-ability students in others; and the like. We therefore ran a multiple regression equation separately for each of the five classes of schools, similar to the basic regression reported in the earlier article. We know from the evidence that student abilities vary substantially among the five classes of schools, but by comparing economics versus no-economics students *within* each class of schools we should gain some indication of how

² Except for the insignificant group noted in the footnote to Table 1.

much the economics courses contribute to after-college test performances holding constant the other factors noted in the table.³

The results are shown in Table 2. Under the heading, "marginal subgroup coefficients," X_1 shows the separate marginal effect of one or two economics courses; X_2 shows the marginal effect of adding one or two additional courses; X_3 shows the marginal effect of adding one or more additional courses to the four already taken. These three figures must be summed to get the full effect of the college economics courses taken in explaining the score on the "Test of Economic Understanding."⁴

Table 2 suggests that, when we hold constant the effects of college class standing (a proxy for ability plus motivation), recency of economics courses, sex, college major, and the like, there remain substantial differences in the contribution made to ex-students' test scores by the five classes of institutions. These vary from a net improvement from having taken economics of 1.95 in 50 large universities to 8.71 in 50 well-known liberal arts colleges (the summation of X_1 , X_2 , and X_3 in each case). It is interesting to note that the net contribution of one or two semesters of economics to later understanding appears to have been small except at the liberal arts colleges, where a substantial marginal improvement came at that level. At the "high prestige" institutions, the biggest improvement came at the three-four course level; while at teachers colleges and other schools the biggest advance occurred only when students took five or more courses. As has been indicated by earlier studies, on the average, student ability tends to be lower among "education" majors than among most other groups of students; this shows up clearly in both Table 1 and in the variable X_{10} coefficients of Table 2.⁵

II

Different hypotheses may be suggested to explain the differences reported in Tables 1 and 2. It is possible, as was suggested in the earlier article, that the test is a poor measure of the amount of economic understanding retained some years after completion of college, or that other unmeasured variables so dominate the amount of understanding after college as to make these results misleading. The counterevidence was presented in the earlier article. We also sug-

³ Although the comparison in Table 2 is only between students within each group of institutions, we did run a separate regression for all students at all schools to measure the relative importance of being a student at each different class of school. This, of course, reflects in some considerable part the differences in student abilities at the different institutions, but reflects other factors as well. Using the data for all schools with a separate variable added for class of school, the coefficient for "prestige schools" is 2.78; for 50 large universities, 2.24; for liberal arts colleges, 1.51; for "teachers colleges," -1.41; and for other schools, -1.36. All results are significantly different from zero at the .01 level.

⁴ For a more complete explanation, see [1, p. 347].

⁵ Comments on, and possible explanations of, some of the coefficients are included in the earlier article. See also [1, p. 347] for comments on the relatively low R^2 s for all the regressions.

Our tests show no significant multicollinearity among the explanatory variables used in the regressions.

* = Significant at .05 level.

gested there (based on the evidence and the psychological literature on learning) that student motivation to learn and to continue using the economics learned in after-college years is essential to obtaining lasting effects from college economics courses.

One further hypothesis, with which the data reported here are consistent, is that the lasting impact of undergraduate college economics courses depends heavily on the emphasis that faculty members put on such teaching, and that this factor is more important than the "quality" of the faculty as measured by the usual criteria of research papers and the like. The smallest lasting improvement from taking undergraduate economics courses appears to come at well-known large universities, where a considerable part of elementary teaching is done by graduate assistants and where many leading professors concentrate on graduate teaching and research. The biggest improvement comes at the 50 well-known liberal arts colleges, where undergraduate teaching is presumably the primary focus of faculty attention, even though the faculty members may not be as "distinguished" professionally as those at some of the 20 "prestige" schools or at some of the other well-known large universities. Interestingly, the next largest contribution appears to come about equally at the 20 "prestige" schools (of which half are small liberal arts colleges) and at the "teachers colleges," where again undergraduate teaching is the primary focus of faculty members and where relatively little teaching is done by graduate students, but where presumably economics faculties are on the average less prestigious in terms of professional standing than those at the first three groups of schools. A breakdown between the liberal arts colleges and the large universities in the 20 "prestige" institutions is consistent with this hypothesis. Although the numbers in the sample so divided are too small to justify placing much weight on the comparison, the level of achievement is slightly higher for the large universities, but the superiority of economics over no-economics students is somewhat larger for the liberal arts college students.

While the results in the study as a whole are mixed, we interpret them as inconsistent with the alternative hypothesis that the students who started from the lowest level of understanding would advance the most through taking economics courses because it is easier to raise such students' understanding from low beginning levels. The results are also clearly inconsistent with the counter hypothesis that the brightest students will be improved the most, even though they start from the highest average level of understanding.

Obviously, the results presented here and in our earlier article are far from definitive on the issues raised. But tentative as they must be, we hope they will be sufficiently provocative to focus attention on the need to improve our undergraduate economics teaching, and equally to stimulate further attempts at careful measurement of teaching results to supplement the impressionistic (and all-too-often wishful) evaluations on which we now rest most of our educational process.

Optimization and Suboptimization in Fishery Regulation: Comment

In the March 1964 issue of this journal, Ralph Turvey states that "if the *optimum optimorum* is to be reached, . . . then (fishery) regulation must extend not only to the scale but also to the mode of operation" [1, p. 64]. He recommends both a toll or charge per pound of fish caught (scale regulation) and the imposition of a legal minimum mesh size (mode regulation) in order to achieve a Pareto-optimum.

If certain implicit assumptions in his argument are made explicit, however, it becomes clear that the necessity for either or both of these regulations is hardly an immutable law of nature. The chief fault in Turvey's otherwise excellent paper is that he does not clearly state the relation between these critical assumptions and his conclusions for public policy. It should be useful to examine in more detail exactly which conditions must be present for one or the other of these regulations to in fact be necessary for a Pareto-optimum.

It is well known that if institutions are such that technological externalities are present, competitive equilibrium will not be Pareto-optimal. Turvey states that two kinds of external diseconomies are present in the kind of competitively organized, single-trawl fishery which he considers. In the first place, a fish caught by fisherman A reduces the stock of fish available to other fishermen, increasing the amount of resources which these others must use to land a given catch. Secondly, a fish caught today by fisherman A will not be around tomorrow as a larger, more valuable fish, again imposing additional costs upon the industry as a whole.

Let the set of all fish in the banks be divided into two subsets: fish that have reached catchable size (called the "fish stock") and fish which have not yet reached that size. The size of the smallest fish in the fish stock is determined by the size of the mesh in nets used by the fishermen. Turvey states [1, p. 65] that operational models used by biologists to assess fisheries commonly make the following assumptions: (a) growth of fish and natural mortality are functions of age, (b) fishing mortality rate (catch) is proportional to "effort," and (c) recruitment into the fish stock, i.e., the number of fish reaching catchable size, is exogenous.

If assumption (c) is taken literally, then "weight recruitment," or pounds of fish reaching catchable size per time period, would depend only on mesh size, since larger mesh would lead to recruitment at a heavier weight. Specifically, the number of fish in the fish stock or the size of the catch would not affect recruitment. It seems reasonable to assume that the number of fish eggs laid per year is proportional to the number of fish in the banks, and that the number of fish hatching is proportional to the

number of eggs laid. If recruitment is to be exogenous, then, mortality in the set of fish which have not reached catchable size must be inversely proportional to the number of fish of egg-laying age, which contradicts assumption (a). It would seem somewhat less fishy to assume that mortality is an increasing function of the number and size of fish competing for food.

The simplest recruitment assumption consistent with (a) and (b) seems to be that natural mortality is a function only of the age of the fish, and that the number of eggs laid per year is determined exogenously. (We will examine the consequences of relaxing this assumption below.) Let the growth

FIGURE 1. GROWTH OF A TYPICAL FISH

of a typical fish be depicted in Figure 1. The solid upper curve shows the growth of the fish as a function of its age, provided the fish lives. The probability that a given fish, once hatched, will have died can be expected to increase as the time elapsed since his hatching grows longer. The bottom dashed curve gives his expected weight (in the statistical sense) when natural mortality has been allowed for.

The size in pounds of the fish as it reaches catchable size is proportional to the cube root of mesh size: thus, the larger the mesh, the older the youngest fish in the fish stock. Given a mesh size of m_0 inches, a fish will be recruited into the fish stock at the corresponding weight w_0 , at age a_0 . The total "weight recruitment" into the fish stock is given by:

$$(1) \quad r = n \cdot w'_0$$

where r = recruitment into the fish stock (lbs./yr.), n = number of eggs hatching per year, and w'_0 = expected weight of typical fish at age of re-

recruitment (lbs.). Given our assumptions, w'_0 is a function only of mesh size, so that equation (1) becomes:

$$(1') \quad \begin{array}{ll} r = r(m) & \text{(recruitment function)} \\ m = \text{mesh size} & \text{(inches).} \end{array}$$

For the individual fisherman, catch (and hence revenue) is a function of mesh size, size of fish stock, and of the resources he expends. Turvey defines an aggregated input called "fishing effort," defined in such a fashion that the fisherman's catch, measured in pounds, is proportional to effort. Effort, then, appears as the argument in the fisherman's cost function. His production function exhibits constant returns to scale if doubling of all inputs results in a doubling of effort as defined. If, in addition, all inputs are available to the industry in perfectly elastic supplies, average cost, *ceteris paribus* (fish stock and mesh size constant), per pound of fish will be constant. If, on the other hand, factor supply curves are not all perfectly elastic, then average cost (again, *ceteris paribus*) will be a rising function of industry output. For the industry as a whole, then, we have:

$$(2) \quad f = g(F, E, m) \quad \text{(industry production function)}$$

$$(3) \quad C = C(E) \quad \text{(total industry cost)}$$

where f = total fish catch (lbs. yr.), F = size of fish stock (lbs.), C = total cost of catching fish (\$), and E = fishing effort (units).

Biological steady-state equilibrium of the fish stock, given the biological environment, depends both on the quantity of fish entering the fish stock (recruitment) and on the quantity of fish removed from the fish stock (catch) each year:

$$(4) \quad F = B(f, r) \quad \text{(biological equilibrium).}$$

Substituting (4) into (2), we have:

$$(5) \quad \begin{array}{ll} f = g(B(f, r(m)), E, m) \\ f = h(E, m) & \text{(sustained-yield production).} \end{array}$$

Equation (5) represents sustained-yield production as a function of mesh size and fishing effort. In other words, it represents a steady-state equilibrium level of catch compatible both with fishing technology and with the biological productivity of the fishing banks.

Turvey assumes that the price of fish depends only on the weight of the industry catch, subject to the condition that all fish be at least of a given "minimum marketable size" [1, p. 67]. Thus, rounding out our model, we have:

$$(6) \quad \begin{array}{ll} P = P(f) & \text{(industry demand)} \\ P = \text{price of fish (\$/lb.).} \end{array}$$

Variations in mesh size can be assumed to be costless. Hence, for any given level of fishing effort, Pareto-optimality requires that mesh size be such as to maximize sustained-yield production. Given our assumptions, however, a fisherman, left to his own devices, will choose a mesh size such that the smallest fish caught is also the minimum-marketable-size fish [1, p. 68]. In Figure 2a, this minimum marketable size is w_{min} , and the corresponding recruitment is as indicated. Legislating a larger mesh size in this case would increase, *ceteris paribus*, costs for the individual fisherman. Since recruitment would be reduced (shown by the downward-sloping $E(w)$ curve), size of the fish stock would actually be reduced, further increasing costs.

In Figure 2b, increasing mesh size would increase recruitment, and thus the fisherman's parameter F . Only if the decreased costs associated with

FIGURE 2a. GROWTH OF TYPICAL FISH: NO MESH-SIZE REGULATION NEEDED

FIGURE 2b. GROWTH OF TYPICAL FISH: MESH-SIZE REGULATION POSSIBLY NEEDED

the increased steady-state fish stock at least offset the increased production costs due to the larger mesh size, however, will a larger mesh size be Pareto-superior. If, and only if, this is indeed the case will external diseconomies of the second type mentioned above exist, and then, and only then, will some sort of regulation of mesh size be necessary for a Pareto-optimum.

Let us now examine the consequences of altering the assumptions that natural mortality is a function only of the age of the fish, and that the number of eggs laid per year is determined exogenously. If both are made functions of the size of the fish stock (F), no new variables are introduced, and the model is not significantly altered. Let the natural mortality (at a given age) and the number of eggs laid per year both vary directly with F . Then equation (1) becomes:

$$(1a) \quad r = n(F) \cdot w_0'(F).$$

$$(1a') \quad r = r(m, F) = r(m, B(f, r)) = r'(m, f).$$

Stated in words, steady-state recruitment now depends both on mesh size and on the size of annual catch. Equation (5) becomes simply:

$$f = g[B(f, r'(m, f)), E, m]$$

$$(5a) \quad f = h'(E, m).$$

As before, sustained-yield catch depends on industry effort and mesh size, although in general the functional form will be different and perhaps more complex. Moreover, the same conclusions hold. If, and only if, increasing mesh size will lower total (steady-state) industry costs will mesh size regulation be necessary for a Pareto-optimum.

More formally, the assumption that variations in mesh size are costless implies:

$$(7) \quad \left. \frac{\partial h}{\partial M} \right|_{\Delta E=0} \leq 0.$$

The strict inequality holds for the case where m is such as to catch fish of minimum marketable size. When equation (7) holds, suboptimization with respect to mesh size has been achieved, and then industry catch can be written as a function solely of industry effort:

$$(8) \quad f = S(E) \text{ (industry sustained-yield catch, given suboptimum mesh size).}$$

Equation (8) describes the "eumetric yield curve" [1, p. 70; p. 66, Fig. 1]. Alternatively, effort expended can be written as a function of fish caught:

$$(9) \quad E = t(f).$$

Since at sufficiently high levels of effort, sustained-yield catch may actually decline (negative industry returns to effort), t may be double-valued.

Benefits derived from the fish stock may be written:

$$\begin{aligned}
 G &= \int_0^f P(f)df - C(E) \\
 &= \int_0^f P(f)df - C[l(f)].
 \end{aligned}$$

Maximizing G , we have:

$$\begin{aligned}
 \frac{\partial G}{\partial f} &= P(f) - \frac{\partial C}{\partial E} \frac{\partial l}{\partial f} = 0 \\
 (10) \quad P &= \frac{\partial C}{\partial E} \frac{\partial l}{\partial f} = \frac{\partial C}{\partial f}.
 \end{aligned}$$

In words, additional fish ought to be caught up to the point where the increment in costs associated with an additional pound of fish just equals the value the market places on that additional pound of fish. In the absence of a toll or charge for the use of the fish stock, long-run competitive equilibrium will be achieved when $P=C/f$, the average cost to the fishing industry.

Now, average cost equals marginal cost only when the former is a constant. If this is the case, additional industry output will be proportional to the extra fishing effort expended. This is equivalent to stating that increases in *industry* output have a negligible effect on the fish stock, and, hence, that the marginal product of the fishing banks is zero. If, however, increases in industry output decrease the fish stock, the marginal product of the fishing banks will be positive. Average cost will be less than marginal cost as defined, and external diseconomies of the first type will be present. If a toll, T , per pound of fish caught is levied, then $P=T+C/f$ is the condition for long-run competitive equilibrium. Hence, from equation (10), optimum utilization of the fishing banks requires that:

$$(11) \quad T = \frac{\partial C}{\partial f} - C/f.$$

In words, a toll should be levied on each pound of fish caught equal to the difference between the marginal social cost ($=\partial c/\partial f$) and the marginal private cost ($=C/f$, the average industry cost in long-run competitive equilibrium). This toll is completely analogous to a rent on any fixed facility, and is exactly equal to the toll that would be collected by a profit-maximizing, perfectly competitive fishing-banks operator, if, indeed, fishing banks were owned by individuals.

It is interesting to note that if the marginal product of the fishing banks is zero, then "type 2" externalities are not present either. For if increasing the industry output has no effect on the fish stock, then fishing mortality is a negligible fraction of total mortality. Increasing mesh size from the minimum would also have a negligible effect on the size of the fish stock. The converse is not true; it is conceivable that "type 1" diseconomies could

exist without "type 2" diseconomies. Thus, (a) no regulation, (b) toll only, and (c) toll plus mesh-size regulation, are three possible optimizing prescriptions, depending on conditions actually encountered.

In the special case where Pareto-optimality does require both scale and mode regulation (case (c)), there is still no necessity to institute regulation by fiat to control mesh size. A penalty toll on all fish in a catch smaller than the size corresponding to the optimum mesh size would accomplish the same end. This fact hints that Turvey's dual recommendation, when valid, is a product of the peculiar technology involved in fisheries. Suppose that fishermen could choose whatever size distribution of catch they wanted, instead of being limited to choosing only the minimum size of fish in the catch. Then, regulation only of the minimum-size fish and of fishing effort would probably not be sufficient for a Pareto-optimum.

In terms of Figure 1, fishermen ought to be penalized for catching fish younger than the maximum expected weight age, and encouraged to devote relatively more effort to older age classes. A variable toll, either continuous or by size class, would be necessary. The actual form of the toll would also depend on the relative costs of landing different-size fish and upon the effects of the fishing activity on the shape of the $E(W)$ curve and on the number of eggs hatching. But, in general, it would not be infinity for fish smaller than a certain size and constant for larger fish.

Shifts in Demand and the Inflation Problem: Comment

Professor W. G. Bowen and Mr. S. H. Masters, in their paper "Shifts in Demand and the Inflation Problem" [1], discuss the relationship between the rate of inflation and the unevenness of changes in demand for the products of different industries. Their inquiry was inspired by Charles L. Schultze's well-known study of the inflation of 1955-57 [2], but their model differs from his in its emphasis on disparate changes in demand rather than differences in the prevailing levels of demand. Bowen and Masters divided the period from January 1947 to March 1963 into six subperiods, chosen to minimize the effects of cyclical factors, but varying in length from 18 to 68 months. For each subperiod, changes in the value of sales of 21 two-digit industries were tested for dispersion by two alternative but closely related measures. One of these measures (I_{st}) required the differences between the average proportional increase in sales and the growth rates of the separate industries' sales to be expressed as absolute values, weighted by the respective contributions of the industries to income originating in manufacturing

and summed. The other measure (I^*_s) is the weighted standard deviation of the different growth rates. The principal conclusions are, first, that there were indeed uncommonly pronounced disparities in demand changes during the period 1955-57 and, secondly, that the period from July 1957 to March 1963 was one in which the disparities were extraordinarily slight. From the latter result, a by-product of the inquiry, Bowen and Masters infer that recent price stability may have been due partly to a fortuitous circumstance.

It is argued in this comment that Bowen and Masters' evidence relating to changes in sales is an unsatisfactory basis for these inferences. The central problem is whether the changes in the money value of sales on which they rely can be accepted as a measure of changes in demand. Although Bowen and Masters draw attention to some defects of their technique, its limitations require greater emphasis. Why does the value of sales in one industry increase at a different rate from sales in another? If both industries are initially in market equilibrium, the following possibilities are perhaps the most important:

1. The two industries, although they have demand and supply functions with similar elasticities, are confronted with unequal movements in their demand curves. In this instance the unequal changes in sales can be attributed unambiguously to unequal changes in demand, and Bowen and Masters' reasoning is justified.

2. Similar movements in the demand curves cause different changes in the equilibrium quantities and prices because demand and supply elasticities differ.

3. Supply functions may change for a variety of reasons, including changes in physical production functions and spontaneous alterations in the costs of factors of production. Wage increases due to union aggressiveness are one example of the latter. Again, unequal movements in sales may ensue either because the separate industry supply functions are unequally affected or because similar changes interact with different demand and supply elasticities.

4. Although the new equilibrium conditions may involve equal proportional changes in sales, the speeds at which industries and their markets respond to changed circumstances may differ. Thus within any period less than that required to reach equilibrium, sales may change at unequal rates.

Relaxing the assumption of initial equilibrium, we encounter two further important possibilities. One is that factors of production previously in limited supply become available, with unequal effects on the output of different industries; the other that, for reasons implicit in factor (4) above, industries inherit from earlier periods unequal pressures to alter their production and prices.

No attempt can be made here to separate the effects of these factors, but the implicit assumption of Bowen and Masters that (1) predominates seems gratuitous. Two hypotheses related to this general reasoning are advanced, however, which give more concrete ground for rejecting their technique. The first is that the measures of dispersion and the rate of increase of prices are strongly correlated. This hypothesis is suggested by the supposition that firms and industries do not respond instantaneously or simultaneously to changes in market conditions; hence they are more likely to behave in a similar fashion

when there is little pressure to change. Moreover, the process of raising prices has a sequential character, as increases in some industries lead to increases elsewhere. In *any* short period of an inflationary nature, therefore, considerable dispersion in the rate of change of sales is likely to be apparent. It can, of course, be objected that the suggested correlation merely confirms the importance of unequal changes in demand as a cause of inflation. This is a logical possibility. The postwar inflation *may* have been due largely to unequal changes in demand, and economists may have been mistaken in emphasizing the role of such pressures as high liquidity, generalized excess demand, and union aggressiveness. A more reasonable interpretation, however, is that the association of varying degrees of dispersion with changing rates of inflation is less a causal relationship than a consequence of the tendencies outlined above. In any event, it becomes difficult to maintain that there was anything special about the periods 1955-57 and 1957-63. Bowen and Masters would need to show that sales changes were even more unequal in the former period and even less so in the latter than the normal relationship between inflation and dispersion would lead one to predict.

The second hypothesis is more straightforward: the degree of dispersion is likely to diminish as the interval of time considered is extended, for the general movement of sales, under conditions of inflation and increasing real output, comes increasingly to submerge short-term changes in prices and output in different industries. If this expectation is confirmed, the Bowen-Masters measures cannot validly be used to compare periods of different length.

Considerable manipulation of the published data is necessary before these hypotheses can be tested, and limitation of time has obliged me to rely on Australian data which, for other purposes, were converted into suitable form. Professor Bowen and Mr. Masters, after reading a draft of this comment, tested the second hypothesis against their data for the United States and have generously allowed me to use their results; they could not, unfortunately, undertake a similar test of the first hypothesis. The disadvantage of using the Australian statistics is perhaps reduced by Australia's diverse experience of inflationary conditions, because of which properties of the Bowen-Masters measures which emerge less conspicuously in the American data may be easier to detect.

The Australian manufacturing industries distinguished in the official statistics have been consolidated in 27 groups,¹ and the two dispersion measures are calculated on this basis for each year from 1948-49 to 1961-62. Statistics of sales are not available and value of output estimates, differing from sales to the extent of inventory changes, are substituted. Otherwise the data appear to be strictly comparable with those used by Bowen and Masters. Table 1 shows both the values of the dispersion statistics calculated for successive annual changes in output and estimates of annual price increases. The latter estimates are obtained by calculating the implicit price index for gross national product

¹ A list of these groups, to be useful for verification or further research, would need to be supplemented by a detailed statement of the various industries consolidated into them. This information is available on request.

TABLE 3—THE RELATIONSHIP BETWEEN BOWEN-MASTERS MEASURES AND LENGTH OF TIME INTERVAL: UNITED STATES, 1947-63

	I_{st}	I^*
January 1947 to July 1948	4.96	7.19
July 1948 to March 1951	3.94	5.00
<i>January 1947 to March 1951</i>	2.86	4.11
March 1951 to July 1953	4.76	5.96
July 1953 to September 1955	2.46	3.17
<i>March 1951 to September 1955</i>	1.89	2.68
September 1955 to July 1957	5.34	6.34
July 1957 to May 1960	1.48	1.99
<i>September 1955 to May 1960</i>	2.57	2.79
May 1960 to March 1963	1.68	2.04
<i>July 1957 to March 1963</i>	1.57	1.94
<i>September 1955 to March 1963</i>	1.60	1.92
<i>January 1947 to March 1963</i>	1.67	1.91

Bowen-Masters measures are merely proxy price indexes, the correlation is sufficient to require considerable caution in deriving inferences, from the dispersion of sales increases, about the importance of structural variations in demand as a cause of inflation.

Tables 2 and 3 show the effect on the Bowen-Masters statistics of extending the time interval examined. In Table 2, relating to Australia, the results of the annual analysis given in Table 1 are compared with dispersion measures calculated for three longer periods. The tendency for dispersion to diminish with the extension of the period is apparent in all of these comparisons. Table 2 combines periods originally studied by Bowen and Masters to allow similar comparisons for the United States, italics being used to designate composite periods. The same tendency emerges, but more conspicuously with respect to earlier periods, lending support to the suggestion that the tendency is due to the effect of inflation in generating short-term dispersion.

The lesson is that better tests of the demand-shift hypothesis are necessary. With the data available, these tests are difficult to devise and it was presumably for this reason that Bowen and Masters experimented with the change-in-sales method. The apparent inadequacy of this technique means that the substantive issues which they attempted to resolve must for the present be regarded as open.

A Theory of the Bargaining Process: Comment

J. G. Cross's theory of the bargaining process is composed of three elements: a theory of decision-making, a theory of expectations, and a theory of learning. The theory of decision-making consists of the maximization of the present value of an expected payoff, in utility terms, and this aspect of Cross's work will not be questioned in the present paper. The theory of expectations, however, will be examined from the point of view of both empirical plausibility and theoretical fruitfulness, and as a result of this analysis a reinterpretation will be suggested. This will be shown to have repercussions not only within the learning part of the model, but also for the predictions of the theory as a whole. It will be argued that the revised model has some relevance to a bargaining situation of considerable theoretical interest and practical importance, which could not otherwise have been treated within the framework of the Cross theory. This is a bargaining situation involving "brinkmanship."

I. Bargainer's Expectations

The particular aspect of the theory of expectations which I would like to examine is that concerning each bargainer's expectations of the other's concession rate. Obviously, relatively simple assumptions must be made about the behavior of such rates if an analytically manageable model is to be built. However, by making the particular assumption that he does, Cross automatically excludes from his theory a particularly interesting case—that of bargaining involving brinkmanship. What I mean here by a brinkmanship situation is one in which a bargainer expects his opponent to make a concession at some point in the future and, in the light of this expectation, is prepared to wait, making no concession himself. Casual observation seems to suggest that this brinkmanship type of situation is one that typically occurs in bargaining processes.

Let us confine our attention, as Cross does, to the pure intransigence case of bargaining, i.e., the case where each bargainer always expects to obtain agreement at his own current demand. Using the Cross notation, we have utility functions $f(q_1)$, $g(q_2)$ defined over the quantity variables q_1 , q_2 where q_1 is I's share of Q , q_2 is II's share, and the total amount of Q is M . Disagreement occurs when the demands $q_1 + q_2 > M$, and the amount of disagreement (i.e., the total concessions which must be made before agreement is possible) is $(q_1 + q_2 - M)$. In his paper Cross supposes that each bargainer expects the other to concede at a certain rate, i.e., he expects the other to make a continuous series of demands with no discrete jumps. Thus, if I

expects II to concede at the rate r_2 , he is expecting that $-(dq_2/dt) = r_2$. However, each expects the other to start conceding, but neither intends making any concession himself. According to Cross, each bargainer immediately begins to modify his expectations of the other's concession rate, since in general

$$\begin{aligned} -\left(\frac{dq_1}{dt}\right)_{t=0} &\neq r_1 \\ -\left(\frac{dq_2}{dt}\right)_{t=0} &\neq r_2; \end{aligned}$$

and hence the expectations r_1, r_2 must change. These new expectations due to learning feed back into the equation by which each made his original optimal choice of q_j , and a new optimal q_j can be found in each case. And what looks like a new optimum to the bargainer who made it, looks like a concession (or retraction) to the other. Hence the r_j are further modified, and so it goes on.

Let us focus our attention on the form of expectations the bargainers are assumed to have. According to Cross's assumptions each bargainer expects the other to concede at a constant rate over future time (although this rate which is constant over future time may in fact change as present time elapses). It is my contention that bargainers are typically faced with a different form of expectation from this one, the difference being one which materially affects the workings of Cross's model.

In practice, each bargainer typically expects any concession to occur in a sudden discrete lump.¹ Thus, in the pure intransigence case where each bargainer expects the other to agree to his own demand, I may expect II to make the whole concession suddenly from q_2 to $M - q_1$ at or before some point in the future, t_2 , and II may expect I to make the whole concession suddenly from q_1 to $M - q_2$ at or before some point in the future, t_1 . Thus if neither bargainer has made any concession up to some point in time which is less than both t_1 and t_2 , the situation is quite consistent with the expectations of each bargainer. Hence, neither bargainer will modify his expectations as a result of the other's failure to concede during this period, as they would under Cross's assumptions. In fact no learning can occur in this case until the time $t = \min(t_1, t_2)$, at which point one of the bargainers must modify his original expectations.

It is here that an interesting asymmetry, which was absent in Cross's theory, arises. Whereas with Cross's theory the bargainers could learn that their estimates of the concession rate were correct or too large or too small, learning in the present theory is confined to discovering that the estimate of the time before the other bargainer concedes completely is too small.

¹ What I am arguing against here is not the assumption of continuity by the use of differential equations rather than difference equations, which is a legitimate analytical approximation, but rather the assumption that the expected rates of concession r_j are independent of future time.

Whereas Cross's estimated concession rates r_i can increase or decrease as a result of learning, the times t_1, t_2 in the brinkmanship theory can only increase as a result of learning.

Bargainers whose expectations run along brinkmanship rather than constant-concession-rate lines are not in a position to engage in the kind of learning process which is basic to the Cross theory. We will perhaps understand this better if we consider both kinds of expectation as special cases of the general case: the expected concession rate of bargainer II is a function of future time, $R_2(t)$. The expected time elapsing before agreement occurs, w , is then given implicitly by

$$(1) \quad \int_0^w R_2(t) dt = -(q_1 + q_2 - M).$$

Following R. H. Strotz [2] and Cross [1], the optimal choice of q_1 is given by the condition that the present value of I's expected payoff, $f(q_1)e^{-aw}$, is a maximum with respect to the choice of q_1 (neglecting any fixed costs of bargaining per period, since these add nothing new in principle to the discussion).

$$\frac{d}{dq_1} f(q_1)e^{-aw} = 0$$

$$\text{i.e.,} \quad f'(q_1) - af(q_1) \frac{dw}{dq_1} = 0$$

$$(2) \quad f'(q_1) + a \frac{f(q_1)}{R_2(w)} = 0$$

since

$$\frac{dw}{dq_1} = \frac{-1}{R_2(w)}.$$

Now $R_2(t)$ is bargainer I's guess at the value of $-(dq_2/dt)$ at time t after the start of the bargaining. After time t_0 has elapsed, I knows the value of $-(dq_2/dt)$ for all $t \leq t_0$, and hence I can learn about the function $R_2(t)$ in the interval $0 \leq t \leq t_0$. However, in order to solve equation (1) for w , for any given q_1 , I will in general have to estimate $R_2(t)$ for $t > t_0$. It may be possible for a bargainer to use the learning about $R_2(t)$ for $t \leq t_0$ to modify his expectation of $R_2(t)$ for $t > t_0$, but it is here that the two special cases arise. These, together with the general case, are shown in Figure 1. This figure displays various assumptions which could be made about the expectations which each bargainer has of the other's concession behavior. The most general assumption would be that bargainer I, say, expects II's demand to be some (well-behaved) function of future time which, in the above notation, will be given by

$$q_2(t) = q_2^0 + \int_0^t R_2(z) dz$$

(where the i th demand of the j th bargainer is q_j^i). Such an assumption is not very fruitful, since it is devoid of any implication regarding the workings of the model. A more restrictive assumption is shown as the Cross case. This involves expecting that the other bargainer's demand will decrease linearly with future time or, in other words, that he will concede at a constant rate. The brinkmanship assumption, on the other hand, restricts the form of expectation in another way. What is expected here is that a time

FIGURE 1. EXPECTATIONS OF CONCESSION BEHAVIOR

will come (t_2) at which the other bargainer will give in to the demand which is being made of him.

Let us examine the effect of learning in the circumstances characterized by the three different forms of expectations represented in Figure 1.

1. In the case of the Cross assumption, any learning about II's concession rate, $-(dq_2/dt)$, for $t > 0$ will, at that particular instant, modify the slope of the line for all future time in an unambiguous way (i.e., the slope is correct or too big or too small at that particular instant).

2. In the general case, any learning about $-(dq_2/dt)$ for $t \leq t_0$ modifies $R_2(t)$ for $t \leq t_0$ and could conceivably be used to make modifications of $R_2(t)$ for $t > t_0$, but not in an unambiguous way. However, if one could develop a reasonable learning model for this general case, then, with any well-behaved R -function, this modification of the Cross theory would presumably yield a determinate solution through the process of utility maximization by each bargainer. (We note that the R -function in the pure brinkmanship case is not well behaved in that it is not differentiable at $t = t_2$.)

3. In the brinkmanship case any learning about q_2 for $t \leq t_0$ does not modify the curve at all if $t_0 < t_2$ and $t = t_2$ is the only point at which it can be modified. A learning model to account for this case would differ from Cross's in an essential way.

We see that as we examine different forms of expectations regarding concessions from the other bargainer, Cross's learning-concession process works in the special case of expected concession rates constant over future time runs into difficulties in the general case of expected concession rates a function of future time, and breaks down in the brinkmanship case. (That is to say, it breaks down in the sense that it would not yield a solution in the absence of a considerably modified learning model.) Thus, bargaining processes in which expectations of brinkmanship are an essential component would require a development of Cross's theory to describe them adequately. We here outline a possible development in this direction.

II. A Brinkmanship Model

In the brinkmanship case, I expects II to give in completely to his own demand, q_1 , after holding out for a time t_2 . Thus, if we apply the principle of utility maximization to predict I's choice of the value of q_1 , we find a limit imposed. With the theory as it stands, utility maximization would require that I demands the largest q_1 which is possible, i.e., $q_1 = M$. Similarly this principle would require II to demand $q_2 = M$. This rather barren position can be avoided by reasoning as follows: I knows that, if q_2^i is II demand, he can have $q_1 = (M - q_2^i)$ immediately, but demands for $q_1 > (M - q_2^i)$ will take longer to obtain (and similarly for II). We suppose, then, that each bargainer expects the time which the other will hold out before giving in completely to be a function of his own demand. I expects $t_2 = F(q_1)$, II expects $t_1 = G(q_2)$. Following Cross in making a linear assumption, we have

$$(3) \quad t_2 = U(q_1 + q_2^0 - M)$$

³ It could be argued that the linear expectations used here and in Cross's theory are not economically plausible since each bargainer knows that no bargain will ever be concluded outside the contract zone, i.e., there should be no finite t_2 corresponding to $q_1 > M$ and no finite t_1 corresponding to $q_2 > M$. (In practice, things are a bit fuzzier than this because neither bargainer knows the size of M exactly.) The linear functions, however, yield a finite t_i for any q_i , however large.

Plausible nonlinear functions expressing the expectations within the contract zone would be, for example:

$$t_2 = \frac{S_1(q_1 + q_2^0 - M)}{(M - q_1)}, \quad q_1 \leq M$$

$$t_1 = \frac{S_2(q_1^0 + q_2 - M)}{(M - q_2)}, \quad q_2 \leq M.$$

Here the times become infinite as the ends of the contract zone are reached. Such refinements are not considered here since they raise many issues which are not directly relevant to the argument of this paper.

$$(4) \quad t_1 = V(q_1^0 + q_2 - M)$$

where U, V can, for the moment, be thought of as parameters.

If we assume discounting functions e^{-at} for I and e^{-bt} for II, then the present value to I of the demand q_1 is $f(q_1)e^{-at_2}$ where t_2 is given by (3). The condition that q_1 maximizes this expression is

$$(5) \quad f'(q_1) - aUf(q_1) = 0.$$

And similarly for II,

$$(6) \quad g'(q_2) - bVg(q_2) = 0.$$

These are the conditions that each bargainer makes, in the light of his own expectations, an optimal demand.

Suppose the original q_1, q_2 at $t=0$ are such that

$$t_2 = t_2^0 < t_1 = t_1^0.^3$$

I cannot do any learning until $t=t_2^0$ and II cannot do any until $t=t_1^0$. Thus, in our case of $t_2^0 < t_1^0$, I is the first to do any learning. At time $t=t_2^0$ I observes that II does not give in and realizes that his expectation of t_2 was wrong. Thus he wishes to revise his estimate, and we may suppose that he comes to the conclusion that he has been associating too low a value of t_2 with each value of q_1 . I's learning will therefore lead to an upward shift in his t_2 -function, although we still must have $t_2=0$ when $q_1=(M-q_2^0)$. The t_2 -function pivots upwards about $q_1=(M-q_2^0)$ as a result of learning. This result follows from supposing that

$$U = U_0 \quad \text{when } t \leq t_2^0$$

$$U = U_1 > U_0 \quad \text{when } t_2^0 < t \leq t_2^1$$

or, in general,

$$(7) \quad U = U_{i+1} > U_i \quad \text{when } t_2^i < t \leq t_2^{i+1}.$$

Similarly, for II we would have

$$(8) \quad V = V_{i+1} > V_i \quad \text{when } t_1^i < t \leq t_1^{i+1}.$$

This then is the basis of a modified learning theory applicable to the brinkmanship case.

³ If I makes the first demand he will have to use an estimate of $q_2^0, q_2=q_2$, say, this being the demand he expects II to make. This yields an expected delay time $t_2=t_2^0$. However, as soon as II's actual demand q_2^0 becomes known (still at $t=0$) q_2^0 is replaced by q_2^0 and t_2^0 is modified to $t_2^0 = U(q_1^0 + q_2^0 - M)$.

Let us examine the workings of this model. After a time $t < t_2$ has elapsed, the present value of I's expected payoff is $f(q_1)e^{-a(t_2-t)}$, and the q_1 which maximizes this is given by

$$f'(q_1) - a \frac{dt_2}{dq_1} f(q_1) = 0,$$

which is identical with (5) above since $dt_2/dq_1 = U$. Hence, although the present value of I's expected payoff is increasing as time passes, the value of q_1 which maximizes it is invariant with respect to time, so long, of course, as the parameters remain unchanged.

The q_1 which satisfies (5) can be thought of as the solution of the pair of simultaneous equations

$$(9) \quad y = f'(q_1)$$

$$(10) \quad y = aUf(q_1).$$

Consider now what happens when I learns at time t_2^0 and increases the value of U . As shown in Figure 2, the function OS will shift upwards to OT , giving a new value for the optimal q_1 , OB . This will be less than the previous value, OA . Thus I makes a concession AB . Here we are faced with a similar

FIGURE 2. THE OPTIMAL-DEMAND DECISION

paradox to that which Cross observed in connection with the intransigence aspect of the theory. Each bargainer expects the other to make complete concessions $q_1 \rightarrow (M - q_2)$ and $q_2 \rightarrow (M - q_1)$, but each himself only makes what are in general partial concessions (like AB). Any change in q_1 could be a complete concession if U increases enough to bring the intersection above or to the left of $q_1 = (M - q_2)$.

When II observes I make a partial concession at a time t_2^0 , he does not regard this as inconsistent with his expectation that I will give in completely at or before $t = t_1^0 (> t_2^0)$. Hence II does not do any learning until $t = t_1^0$, in which case V increases, giving a new value for $t_1 (t_1^1 > t_1^0)$,⁴ and a new optimal q_2 less than the previous one.

Thus, since each change of demand by one or the other bargainer represents a partial concession and not a retraction, the learning-concession process should lead eventually to an agreement. A learning theory consistent with (7) and (8) but giving the actual changes in U , V , and hence in t_1 , t_2 , would enable a solution to be derived.

Whereas in Cross's original version changes in demands could be concessions or retractions, in this brinkmanship version of the theory, all the changes in demands are concessions. The reason for this is that when a bargainer gets to the time at which he expects a complete concession, he can learn that his estimate of the time was correct (if the other gives in) or that it was too small (if the other does not give in). Thus, learning in the brinkmanship model always consists in increasing the expectation of the time t_1 (or t_2), i.e., in increasing U or V . (In Cross's theory the rates r_1 , r_2 could increase or decrease as a result of learning.) Thus, the function $y = aUf(q_1)$ can shift upwards but not downwards. Since $y = f'(q_1)$ is a strictly decreasing function of q_1 , by the assumption of diminishing marginal utility, we can see that if $y = aUf(q_1)$ (which is a strictly increasing function of q_1) shifts upwards, it must always intersect $y = f'(q_1)$ at a smaller value of q_1 , i.e., the change of q_1 , being a decrease, represents a concession and not a retraction.

This analysis may cast some light on one of Cross's comments. He says [1, p. 76]:

Often, retraction of an offer during negotiation is thought to be either unethical or at least undesirable because of the unfavorable utility shifts which such behavior may induce in the other player. . . . Nevertheless, such retractions sometimes occur in practice. We will, therefore, retain the possibility of their occurrence, recognizing that forces probably exist which discourage increases in demands during the course of negotiations.

It seems that the model here developed displays the forces which discourage increases in demands during the course of the negotiations by taking into account the brinkmanship aspects of the bargaining process.

⁴ In order for $t_1^1 > t_1^0$ we require that $dh/dq_2 < 0$, since q_2 cannot increase over time. It can be shown that a sufficient condition for this is $t_2 > 1/a$. (In fact this is a rather strong condition and, in general, t_2 does not have to be as large as this for the condition to hold.) Similarly, we require $t_1 > 1/b$. To simplify the analysis we assume that these conditions are satisfied.

In summary, it seems that one aspect of Cross's model which is over-restrictive, in the sense that it appears openly inconsistent with casual observation, is the assumption of the expectation of a rate of concession independent of future time. However, it would appear that, with the type of modifications suggested above, the essence of Cross's argument would remain. It would still be possible, as has been indicated, to construct a determinate, descriptive theory of the bargaining process based on the utility-maximizing behavior of individuals.

A Theory of the Bargaining Process: Reply

There is little doubt that concessions during the bargaining process are composed of discrete lumps. The presence of indivisible components of the payoff is by itself sufficient for this conclusion and furthermore there is substantial evidence that bluffing behavior tends to bring about discontinuous changes in explicit demands as well. Alan Coddington's primary objection to my model is not that assuming a constant concession rate makes for a poor approximation to discrete reality, however, but rather that even "casual observation"(!) suggests that negotiators expect no concessions at all until a time of utter capitulation is reached. Since expectations themselves are generally not observable under any but the most carefully controlled experimental circumstances, I conclude that Coddington is inferring his hypothesis from observations of bargaining *behavior*. This, then, is in part an empirical question. Of course one can find many examples of negotiations in which initial demands are preserved over considerable periods before any concessions are made. These circumstances, however, need not be associated with discontinuous expectations, for they are easily attributable to the presence of bluffing behavior and to the absence of any substantial disagreement costs as well (e.g., the strike date may still be six weeks away and, although initial positions have been outlined, serious negotiations have not yet even begun). Furthermore, both logical and empirical considerations lead me to be skeptical about Coddington's hypothesis:

1. Coddington's own model predicts that the negotiators will concede continuously after some point in time. Logically, it is hard to see why experienced negotiators would not come eventually to *expect* such behavior.

We are asked to accept a model in which an individual's expectations lead to outcomes which are fundamentally different from those anticipated, and yet in which subsequent negotiations are approached with expectations which are unchanged from their original form! Coddington attempts to avoid this dilemma by assuming that each player simply disregards any of his opponent's concessions which fall short of utter capitulation, but again one must be nagged by the realization that each player knows that his own concessions *do* reflect his own preferences and expectations, and hence that they should not be disregarded.

2. Experimental evidence does not support Coddington's suggestion that a substantial period will pass without serious concessions. For example, Figure 1 contains a plot of a typical case from Siegel and Fouraker's [2] bargaining experiments.¹ Concessions here take place immediately and, in fact, they are virtually continuous.

3. Empirical studies place so much significance upon the *sequence* of concessions that it is hard to believe that they would not be taken seriously by the negotiators themselves. For example, in a recent study, R. W. Walton and R. B. McKersie specifically state that "the alternation of concessions is not a mechanical process. *Each side is alert to the meaning of the other's concession*" [3, p. 88, italics added]. That is, not only are concessions *expected*, but they are deliberately analyzed for new information.

A related point deals with Coddington's suggestion that even very large concessions coming long before the expected capitulation date will not influence the behavior of a negotiator. This position also appears to be implausible on empirical grounds. For example, Walton and McKersie devote some time to the dangers of "signalling weakness" to an opponent through one's own concession behavior [3, pp. 89-90]. Furthermore, as Coddington realizes, his hypothesis would preclude the retraction of bids during negotiations—a phenomenon which is far from uncommon in experience. I am afraid that Coddington has misinterpreted those statements which I made regarding the retraction of bids, and which he has quoted in his *Comment*. I was by no means searching for economic forces which could prevent "undesirable" demand retractions. In fact, it should be emphasized that my statements were meant to reflect my decision to reject just such a model as Coddington has proposed. The point is that any mechanistic model of behavior must either introduce psychological variables relevant to the environment in which the operation takes place or it must not be construed to cover situations in which that environment is likely to be altered drastically. Retractions can generate resentment, and the resulting change in psychological atmosphere can alter the whole course of the bargaining process. (Indeed, in many historical cases, it has.) Thus I was not seeking a device to *prevent* retractions, but rather was expressing doubt that their extent and frequency could be described adequately without a more psychologically-oriented model.

Coddington states that his modifications do not affect the determinacy of the model. This is not strictly true. Although his model does have a determinate solution, his refusal to permit intermediate concessions to influence the learning process has eliminated a crucial interdependence which was present in my original formulation. Suppose that we consider one bargainer in Coddington's model. This individual makes a bid, say q_1^0 , which he maintains over a period t_0 ; after t_0 , if his opponent has not already capitulated, he begins to concede regardless of what his opponent may be doing. If the other never concedes at all, the first player will eventually give in all the way to $q_1 = M - q_2^0$. The important point is that, under Coddington's formulation, *until agreement is reached, each player's time path of concessions is completely independent of the other's behavior*, and, in fact, each player's concessions are determined solely by his own initial expectations and by the nature of his own learning process. The outcome, of course, is dependent upon the same variables. A major aspect of my own model was the demonstration of the existence of an equilibrium process

during negotiation, such that within the limits imposed by the finite time dimension of bargaining, the outcome is *independent of initial expectations* (and hence of the initial demands). Of course, neat dynamic properties of economic models cannot be taken as indicators of their empirical validity, and for this reason, it would be unfair to cite these properties as a criticism of Coddington's comment. Nevertheless, I think this distinction between the workings of the two models is extremely important; if the equilibrium process does not hold, we must conclude that random variations in initial expectations are directly reflected in bargaining outcomes, and our hopes of constructing a model, capable of reasonably accurate prediction, must be greatly dimmed.

Finally, the generalized expected-concessions function, $R(t)$, is a useful addition to the theory. As Coddington points out, it is not difficult in principle to deal with this function. The learning model can be simpler than he supposes, however. For the simple model, we needed only the learning condition that the expected concession rate was increased whenever actual concessions were found to exceed expectations, and vice versa. In the general case, when the expected rates are found to underestimate reality, we would have the value of

$$\int_0^{q_1+q_2-M} \frac{1}{R(t)} dq,$$

decreasing for all values of (q_1+q_2-M) . (Although Coddington does not mention it, it is likely that the function $R(t)$ is dependent upon M as well as upon time and the learning process.) The model can then be carried through just as before, with the forms of the $R(t)$ functions becoming important additional parameters in the determination of negotiation outcomes. For example, it can be shown (if it is not already obvious) that, even if the two parties expect the bargaining process to take the same total amount of time, the outcome, *ceteris paribus*, will be biased against the party who expects his opponent to concede at the higher initial rate.

Windfall Income and Consumption: Comment

The purpose of this comment is to suggest a reconciliation of the contradictory findings of Ronald Bodkin [1, pp. 602-14] and M. E. Kreinin [5, pp. 388-90] published earlier in this *Review*. Bodkin's findings, which were based on the 1950 Survey of Consumer Expenditures of the Bureau of Labor Statistics, revealed that the marginal propensity to consume out of windfall income (MPC^w) is of the same order of magnitude as the marginal propensity to consume out of current income (MPC^c). These findings are at variance with Friedman's permanent income hypothesis [3] [4] and were challenged by Kreinin who found that MPC^w , as computed from the 1957/58 Israeli Saving Survey, was about 0.17 or only about a quarter of the MPC^c estimate (0.80).

Bodkin attempted [2, pp. 445-47] to reconcile this contradiction by advancing some arguments which he thought explained the low MPC^w in Israel. First, during the period of the Savings Survey, various exchange rate restrictions were in force in Israel, but recipients of German restitution payments enjoyed a number of privileges as long as they held the money in special accounts. According to Bodkin this provided an incentive to save the restitution receipts. Second, expectations of devaluation induced the restitution recipients to hold their money in liquid assets linked to the foreign exchange rate. These are Bodkin's main arguments, but he noted two secondary factors.

First, he doubted whether it was correct to classify restitution receipts as windfall income, since there were prolonged negotiations before the money was received. The second factor was that the "restitution recipients had as a group experienced many hardships (and worse) during an earlier period of their lives. It seems quite likely that such experiences would make individuals cautious, alert to adverse possibilities, and hence less likely to spend a one-time receipt than would be likely for a group of young American veterans."

We shall attempt to refute these arguments in the light of some additional tests we have made. However, apart from the empirical evidence, we suggest that Bodkin did not interpret correctly the possible effect of the Israeli exchange rate restrictions on consumption out of restitution receipts as compared with the marginal propensity to consume out of current income.

We believe that the reason for the discrepancy between the results of Bodkin and Kreinin lies in the relatively small sums which served as windfall income in Bodkin's data—about 7 per cent of current income on the average—while in Kreinin's data the restitution receipts were of the same order of magnitude as current income of the recipients. This is an important difference, as our findings suggest that the marginal propensity to consume out of windfall income (MPC^w) decreases strongly as windfall income rises.

I. *Some Reflections on Bodkin's Explanation of Kreinin's Findings*

We shall start with Bodkin's last argument that the MPC^w of restitution recipients is especially low because these were people who had experienced an extremely hard life. In order to test this hypothesis we took out of the 1963/64 Family Expenditure Survey¹ all the families who had received any lump-sum income in 1963-64 and divided this group into two: restitution recipients and others. There were 82 families in the first group, and 170 in the second. In each group we ran a regression of the form:

$$(1) \quad C = \alpha_0 + \alpha_1 Y + \alpha_2 N + \alpha_3 P + u,$$

where C is family consumption² expenditure; Y is family current income; N is family size; and P is restitution receipts or other³ windfall income.

If Bodkin's argument holds, the estimate of α_3 obtained from the first group should be significantly lower than that obtained from the second group. But the results revealed that the estimates did not differ significantly. MPC^w for the first group was 0.2603 (± 0.0744) and for the second 0.2544 (± 0.050). We think that these results disprove Bodkin's hypothesis concerning different consumption behavior of restitutions recipients.

We shall turn now to Bodkin's argument⁴ that it was not legitimate to classify the restitution receipts as windfall income because the typical restitution payment did not surprise the recipient, since it had been subject to prior negotiation. We think that his reservation on this point is reasonable on the grounds that if people look forward to a windfall for some time they may well increase their consumption on account of it (perhaps by taking loans); when they actually receive the windfall the net increase in their wealth is therefore less than the total windfall, and the estimate of MPC^w is downward-biased. If this is so, restitution payments received in period $t+1$ should affect consumption expenditure in period t .

In order to test this we took out from the Israeli 1958/59 reinterview Savings Survey⁵ all families⁶ who received windfall income in 1958-59 and

¹ See Appendix.

² Throughout this paper durables are included in consumption expenditure otherwise cited. The exclusion of durables did not affect the conclusions, the results in this case being $\alpha_3 = 0.2050$ for restitution recipients and 0.1695 for recipients of other kinds of windfall income.

³ Other windfall incomes consisted of severance pay by employers, lottery prizes, local legacies in cash, cash gifts from abroad, domestic cash gifts, and lump-sum National Insurance gratuities.

⁴ Bodkin has another objection to the classification of restitution receipts as windfall income: "the restitution payments might be considered analogous to insurance receipts, as they were intended to be partial compensation for losses sustained by the individual in the past. Thus, some individuals might have regarded their receipts as similar to a return of capital and hence might have been less prone to consume out of such a receipt." As the restitution receipts were intended to be a partial compensation for loss of families and wealth during the Second World War we do not think Bodkin's argument sound in this case.

⁵ See Appendix.

⁶ To be exact those were investigation units the number of which differed by about 5 per cent. We had no information on which of them received restitution payments, but as these account for about two-thirds of total windfall income, the possible error probably can be neglected.

TABLE 1—INCOME AND CONSUMPTION OF FAMILIES 1957-58
(Yearly averages in £)

	(1) Number of Families	(2) Current Income	(3) Windfall Income in 1957-58	(4) Consumption Expenditure	(5)* Adjusted Consumption Expenditure
Received windfall income in 1958- 59	161	3,764	798	3,602	3,602
Did not receive windfall income in 1958-59	799	3,233	388	3,040	3,564

* The estimates for adjusted consumption expenditure excluding durables were 3,336 and 3,290, respectively.

computed their consumption expenditure in 1957-58. We made the same calculation for families who did not receive windfall income in 1958-59.

But as these two groups received different amounts of current and windfall income in 1957-58 we made a computation which allowed⁷ for these differences. As column (5) in Table 1 shows, future windfall income did not affect current consumption.⁸ In order to test this result in a different way we ran a regression of the form:

$$(2) \quad C_t = \beta_0 + \beta_1 Y_t + \beta_2 W_t + \beta_3 W_{t+1} + v_t,$$

where C_t is consumption expenditure in 1957-58; Y_t is current income in 1957-58; W_t is windfall income in 1957-58; and W_{t+1} is windfall income in 1958-59.

The results presented in Table 2 reveal that the value of the MPC out of future windfall income is extremely low, not different significantly from zero. These findings confirm our conclusion that consumers behaved as if they did not expect⁹ any lump sum; these receipts in our data can therefore

TABLE 2—MARGINAL PROPENSITIES TO CONSUME OUT OF CURRENT AND WINDFALL INCOME

	MPC out of Current Income	MPC out of Windfall Income	MPC out of Future Windfall Income
Consumption-expenditure	0.7609 (±0.0173)	0.1881 (±0.0245)	-0.0038 (±0.0224)

⁷ We multiplied the differences between these two groups in current and windfall income by their respective MPC and added this to 3040 thus receiving 3564.

⁸ The same results were obtained for real estate purchases.

⁹ We can interpret these results in another way: one could argue that although receipts were expected, consumers were not able to realize them. This interpretation, however, does not contradict our conclusion. What is important for us is the fact that these receipts did not affect consumption until the recipients got them.

be classified as windfall income not causing any bias in the estimate of MPC*.

We now come to Bodkin's two principal suggestions about the low MPC* in Kreinin's paper: "the restricted portion (80 per cent) of the restitution receipts might have been saved, by at least some recipients, in anticipation of a devaluation of the Israeli pound, as it was well known that the official exchange rates overvalued the currency." Concerning the second part of the receipts, Bodkin says that "there were economic pressures to defer consumption out of the unrestricted (1/5) portion of the restitution payments. With foreign exchange restrictions, an individual recipient would not have been able to obtain in the future unlimited foreign exchange for personal use. Consequently, he might have deferred consumption out of at least a fraction of this portion also."

We believe that Bodkin's second argument might be valid, but as it is relevant to only 20 per cent of the receipts it cannot explain the very large discrepancy between his and Kreinin's findings. But as regards to devaluation expectations, which affected the predominant share of the receipts, Bodkin ignored the fact that any Israeli could acquire various liquid assets linked to the foreign exchange rate, and thus hedge against devaluation. Consequently, we see no reason for such expectations to affect the ratio MPC*/MPC*.

We shall now attempt to refute Bodkin's conclusion about the magnitude of MPC*, with the help of data from the 1963/64 Family Expenditure Survey and the 1958/59 reinterview Savings Survey.

Since the devaluation of February 1962, there has hardly been any advantage in holding restitution money in the form of liquid assets, so that there is no longer any reason for restitution recipients to defer final allocation of their lump-sum receipts¹⁰ as far as concerns speculation about possible devaluation. If we are right in rejecting Bodkin's interpretation, we should thus obtain results similar to those in Kreinin's paper. In order to test this, we used the data of the 1963/64 Family Expenditure Survey and computed a regression of the form:

$$(3) \quad C = \gamma_0 + \gamma_1 Y + \gamma_2 N + \gamma_3 W + e,$$

where C is current consumption expenditure; Y is current income; N is family size; and W is restitution receipts.

The results were $\gamma_1 = 0.8397 (\pm 0.0712)$ and $\gamma_3 = 0.2603 (\pm 0.0744)$, confirming Kreinin's findings.

Table 3 presents additional evidence. It shows that in 1958-59 there was a time lag in the final allocation of restitution receipts, but the final allocation is not as indicated by Bodkin. In fact the time lag hardly affects the allocation of the restitution payments between consumption and savings. The time lag is important in final allocation of restitution receipts as regards the structure, but not the amount of savings. Of the 45 per cent of restitu-

¹⁰ After the devaluation the price level continued to rise moderately by 5-6 per cent each year, but as far as we know there is no evidence that this has anything to do with the marginal propensity to consume out of any income.

TABLE 3—LUMP-SUM PERSONAL RESTITUTION PAYMENTS FROM GERMANY AND THEIR
USE 1957-58 TO 1958-59
(Per cent of amounts received)*

Use of Funds	Restitution Payments Received in 1957-58		Restitution Pay- ments Received in 1958-59
	Expenditure in 1957-58	Expenditure in 1958-59	Expenditure in 1958-59
Current consumption	17	4	18
Durable consumer goods	9	4	18
Real estate	20	25	40
Financial assets	45	-33†	22

* Percentage figures do not add up to 100 as not all uses were included in this table.

† Excluding accumulated interest.

tion receipts used in the first year to acquire financial assets, 25 per cent was spent a year later for real estate, and 4 per cent each on durables and current consumption.

We believe that these results are such as to refute Bodkin's attempted reconciliation of the contradictory findings, and we shall now endeavor to show that the differences between Kreinin's and Bodkin's results stem from the disparity in the amounts of average windfall incomes in their data.

II. *Marginal Propensity to Consume out of Windfall Income (MPC^w)*

From the 1958/59 Saving Survey, which was a reinterview survey, we chose all families who received lump sums in at least one of the years. We then combined the data for both years and adjusted them for the rise in prices. In this way we got about 300 families.

These 300 recipients of lump sums were classified into five groups of w/y , in ascending¹¹ order.

As may be seen from Table 4, by using this classification we got approximately five equal current income (y) groups, which differed as regards the average windfall income (w). For each group we computed a regression of the form:

$$(4) \quad C = \delta_0 + \delta_1 Y + \delta_2 N + \delta_3 W + w.$$

The notation is as before. The result was a strongly decreasing coefficient of w , which means a decreasing marginal propensity to consume out of windfall income. This, we believe, accounts for the differences between Bodkin's and Kreinin's findings.

An unexpected result in this connection is the high value of MPC^w in Group I. We can offer no convincing explanation for this as yet and are

¹¹ Each group contains also the families of the lower groups, so that the groups are cumulative.

TABLE 4—MPC OUT OF CURRENT (y) AND WINDFALL (w) INCOME BY w/y GROUP

Group	Number of Families Cumulated	Annual Current Income per Family (£)	Windfall Income per Family (£)	$\frac{w}{y}$ %	MPC out of:		
					Current Income	Family Size	Windfall Income
I	103	4,312	300	7	0.710 (± 0.061)	127.4 (± 124.0)	1.972 (± 0.772)
II	151	4,449	617	14	0.746 (± 0.050)	194.9 (± 109.1)	0.583 (± 0.276)
III	184	4,429	894	20	0.720 (± 0.043)	193.2 (± 104.6)	0.450 (± 0.177)
IV	247	4,383	1,696	39	0.745 (± 0.034)	174.1 (± 85.9)	0.244 (0.070)
V	297	4,243	2,830	66	0.751 (± 0.034)	197.4 (± 95.9)	0.233 (± 0.035)

trying to analyze the behavior of this group by using additional variables. It is possible that those who receive very small sums as windfall income spend them with little thought, thus behaving in a manner different from that which economic theory generally considers to be rational consumer behavior. However this is only conjecture. In any event the extremely high MPC^w (1.972)¹² in Group I does not invalidate our conclusions about the reconciliation of Bodkin's and Kreinin's results.

As current income per family and family size are almost the same in all five of the groups of Table 4, we can regard these groups as similar with respect to their permanent income, except for the lump-sum effect. If this is the case, the decreasing MPC^w implies a decreasing marginal propensity to consume out of permanent income, where permanent income Y_p is defined as: $Y_p = rT$ (r is interest rate, and T is total wealth). In our case, the windfall can be regarded as an increase in T ($w = \Delta T$), and therefore a decreasing MPC out of W implies a decreasing MPC out of Y_p .

MICHAEL LANDSBERGER*

¹² This high value of MPC^w is not significantly different from unity.

* The author is a senior economist in the research department of the Bank of Israel. He is indebted to Dr. Nissan Liviatan of The Hebrew University, who read an earlier draft of this comment and offered many valuable comments, as well as to Dr. Ronald Bodkin for his helpful critical remarks. Responsibility for any possible errors and deficiencies lies of course with the author.

APPENDIX

The 1958/59 Saving Survey was a reinterview survey and covered about 1000 Jewish urban families. The original Saving Survey covered the period 1957-58 and embraces 3000 Jewish urban families.

The methods and definitions used in the Survey¹³ are very similar to those in the Oxford Saving Surveys and in the U.S. Surveys of Consumer Finances.

The 1959/60 and 1963/64 Family Expenditure Surveys were carried out by the Central Bureau of Statistics¹⁴ and covered each about 1600 urban wage and salary earning families.

The 1963/64 survey included also information about saving items.

¹³ The surveys were carried out jointly by the Bank of Israel, Central Bureau of Statistics, Department of Economics of the Hebrew University, Falk Project for Economic Research in Israel, and Israel Institute of Applied and Social Research. The most important findings and definitions are presented in Bank of Israel *Bulletin No. 10* and Bank of Israel, *Annual Report 1959*, pp. 319-27.

¹⁴ See "Family Expenditure Surveys (1950/51-1956/57-1959/60), Special Series No. 148 Central Bureau of Statistics, Jerusalem 1963. Results of the 1963/64 Survey will be published by the Central Bureau of Statistics.

Windfall Income and Consumption: Reply

Michael Landsberger is to be congratulated on a stimulating, insightful comment. Although I am not completely convinced that differences in the magnitude of the average one-time receipt (relative to average "regular" income) is the full explanation of the divergent results obtained by Kreinin [6] and me [2], nevertheless I believe that Landsberger's discussion throws some new light on these issues.

Landsberger's explanation of the different results found in the studies of Israeli restitution payments and American National Service Life Insurance (herein abbreviated NSLI) dividend receipts is based on the hypothesis that the marginal propensity to consume windfalls is not constant, but instead decreases as the size of the windfall increases. Hence one could argue that the same consumption relationship characterizes both groups of recipients of windfall income, the differences in the observed MPC's merely reflecting the position (in the two separate cases) of the typical recipient of windfall income on the common curvilinear relationship. Landsberger attempts to test this hypothesis, using Kreinin's and some addi-

tional data on Israeli recipients of restitution payments made by the West German government. It should also be possible to make a similar test of this hypothetical relationship on the basis of the selected sample of the NSLI dividend recipients analyzed in [2].

In this sample of 1414 veterans, the size of the dividend payment varied substantially—from as little as \$60 to well over \$1000. Accordingly, it was possible to break the sample into two subgroups which depend upon the size of the dividend received. The sample was divided into two subsamples in the following manner: all NSLI dividend recipients (in the original selected sample) who received dividend payments of \$300 or less were put into Group A; the remainder (those whose dividend payments exceeded \$300) were put into Group B. (Hence, unlike the groups studied in Landsberger's Table 4, these groups are mutually exclusive.) As was the case in the original analysis of these data, consumption behavior is analyzed for the two separate cases in which consumption is defined to include expenditures on durable goods (these results appear in Table 1) and the case where consumption is defined net of expenditure on durables (Table 2). Let C denote household consumption (either concept), y "regular" household disposable income (not including the receipts of NSLI dividend payment), and d the amount of the NSLI dividend payments received by the household in question. For both Group A and Group B, one can calculate regressions of the form:

$$(1) \quad C = \alpha_0 + \alpha_1 y + \alpha_2 d + u,$$

where the α 's are parameters, and u represents a stochastic disturbance.¹ This was done, and the results appear in Tables 1 and 2. Although the columns of these tables are largely self-explanatory, it may be pointed out that the numbers in parentheses, which appear immediately beneath the reported regression coefficients, are the associated standard errors of these coefficients. Also, as is conventional, R^2 denotes the coefficient of multiple determination (uncorrected for degrees of freedom) of the respective regression.

It should be observed that there are substantial differences in the mean NSLI dividend payment d received by the two groups: Group B received, on the average, almost three times as large a payment as did Group A, and even relative to its somewhat larger mean "regular" income, Group B received more than $2\frac{1}{2}$ times as much of this one-time payment. The results of Tables 1 and 2 lend no credence to the hypothesis of a declining marginal propensity to consume windfall income. Taken at face value, the point estimates suggest that the marginal propensity to consume windfall income increases with the size of the windfall. Fortunately, the standard errors are large enough to swamp this theoretically embarrassing possibility,

¹ At present I think that a more sophisticated analysis is required in order to make a tighter test (than was done in [2]) of the proposition that the marginal propensity to consume transitory income (which is not the same thing as a windfall or windfall income) is zero. Roger Bird and I have attempted to carry out such a test in [1]. But for present purposes (examining the issue of a declining marginal propensity to consume windfall income), the less sophisticated analysis is probably satisfactory.

TABLE 1—RESULTS OF THE SUBGROUP CONSUMPTION REGRESSIONS WHEN CONSUMPTION INCLUDES EXPENDITURES ON DURABLE GOODS

Group	Size of Group	Mean y	Mean d	Ratio of d to y (for the Means)	α_0	α_1	α_2	R^2
A	990	\$3,699	\$164	4.4%	\$ 873	0.779 (0.022)	0.782 (0.445)	0.559
B	424	4,213	468	11.1	1,141	0.713 (0.027)	0.907 (0.303)	0.621

TABLE 2—RESULTS OF THE SUBGROUP CONSUMPTION REGRESSIONS WHEN CONSUMPTION EXCLUDES EXPENDITURES ON DURABLE GOODS

Group	Size of Group	Mean y	Mean d	Ratio of d to y (for the Means)	α_0	α_1	α_2	R^2
A	990	\$3,699	\$164	4.4%	\$ 952	0.583 (0.016)	0.157 (0.324)	0.571
B	424	4,213	468	11.1	1,183	0.532 (0.021)	0.563 (0.236)	0.601

and the only justifiable conclusion from this particular test appears to be one of an insignificant difference in the coefficients of d for the two groups.

The conclusion that the marginal propensity to consume the windfall NSLI dividend payment does not decline with an increasing size of this receipt might merely reflect, for the previous test, the choice of the level of the windfall at which to break the selected veterans sample into subgroups. Accordingly, an alternative test of the possible nonconstancy of the MPC out of d can be tried. One can compute regressions of the form:

$$(2) \quad C = \beta_0 + \beta_1 y + \beta_2 d + \beta_3 d^2 + v,$$

where the β 's are parameters and v denotes a stochastic disturbance. In this case, the marginal propensity to consume the windfall receipt d is given by:

$$(2) \quad \frac{\partial C}{\partial d} = \beta_2 + 2\beta_3 d.$$

TABLE 3—RESULTS OF REGRESSIONS OF THE FORM (2), 1,414 MEMBERS OF THE SELECTED VETERANS SAMPLE, ALTERNATIVE DEFINITIONS OF CONSUMPTION

Concept of Consumption Employed	β_0	β_1	β_2	β_3	R^2
Includes Expenditures on Durable Goods	\$964	0.747 (0.017)	0.962 (0.443)	0.00001 (0.00051)	0.601
Excludes Expenditures on Durable Goods	969	0.560 (0.013)	0.645 (0.332)	0.0001 (0.0004)	0.602

A systematic tendency for the marginal propensity to consume the NSLI dividend to decrease with the size of this payment would be indicated by a (statistically significant) negative estimate of the parameter β_3 . The results of two regressions (with alternative definitions of consumption), for the entire 1414 observations of the selected veterans sample, are presented in Table 3. As in Tables 1 and 2, the numbers in parentheses under the estimated regression coefficients are their associated standard errors.

As with Tables 1 and 2, there is no evidence to support the proposition of a declining marginal propensity to consume the windfall receipt. Again, the perverse effect is swamped by large standard errors. Parenthetically, it may be observed that the value of β_3 estimated for the case in which consumption is defined to include expenditure on durable goods seems as close to the hypothetical zero of the null hypothesis as one ever attains in an uncertain world. Nevertheless, these results should not be interpreted to imply that the apparent constancy of the MPC to consume the windfall would hold from zero to infinity. It seems reasonable to believe that this MPC would eventually decrease. However, such a decline appears to be rather slow (that is, it does not appear to take hold within the observed range of variation in the dividend receipts for the selected veterans sam-

ple). Accordingly, it seems questionable whether the differing results obtained by Kreinin and Landsberger for Israeli restitution payments are in myself for these data are wholly explicable in terms of the differing relative magnitudes of the average one-time payment.

Leaving these questions aside, one can return to the larger issue of the comparability of the two sets of data. Landsberger attempts to answer my argument that restitution-payment recipients might display a great degree of intrinsic thriftiness, especially with regard to one-time payments, by "controlling" on a group of Israeli recipients of "other windfall" (non-restitution payments) income. Such a "control" regression is, in my view, largely beside the point. Israel is a country of refugees, and few indeed are the nonnative-born citizens of this country who have not suffered from some form of religious discrimination. One might well expect the same sense of thriftiness, caution, and orientation toward security to characterize most of the citizens of this country, not only restitution-payment recipients. There are the larger questions as well of institutional differences among the two economies.² Thus, Landsberger notes that "after devaluation the [Israeli] price level continued to rise *moderately* by 5-6 per cent each year. (Emphasis added.) Such a rate of inflation would hardly be moderate in the United States. Another institutional difference, one mentioned by Kreinin in [6], is a differing availability of consumer goods on domestic markets. Such institutional differences suggest that one might expect to find some behavioral differences in the two economies, and that differences in the response to two differing kinds of one-time payments are hardly surprising.³

Finally, it seems worth pointing out that Landsberger's results do not constitute a particularly strong confirmation of the permanent income hypothesis, at least in the form in which Milton Friedman has cast it in [4] [5]. As Landsberger notes, the declining marginal propensity to consume windfall payments does imply a declining marginal propensity to consume permanent income, because in Friedman's recent statement of his "horizon" model [5], the former payments are a constant fraction of the latter. Moreover, under the permanent income hypothesis, the failure of future restitution payments to influence current consumption is puzzling to say the least. For under this theory of consumer behavior, the consumer might be expected to write up his wealth and to consume more immediately

² At the time [3] was written, I was not aware of the existence of domestic Israeli bonds linked to the consumer price level or the foreign exchange rate. However, one can still argue that, even with the existence of these hedges, the easiest way to take advantage of an impending devaluation was simply to wait to convert the restricted portion of one's restitution payment. As for the postdevaluation experience, it can always be argued that the experience of one devaluation might reinforce the expectation of another one sometime in the future, particularly if domestic prices were still rising more rapidly than those of one's trading partners.

³ Moreover, one can argue that the two types of receipts are quite different in character. Thus, as was argued in [3], it is questionable whether the restitution payments were considered (by the recipients) as a genuine windfall, or merely as a partial compensation for past losses. It can further be argued that such a receipt is much less likely to be devoted to consumption expenditures than a genuine windfall which does not merely offset (in part) past losses.

upon learning news of an unanticipated payment which will reach him in the near future.⁴ In other words, the permanent income hypothesis would predict that the coefficients of W_t and W_{t+1} in Landsberger's equation (2), β_2 and β_3 , respectively, would be almost equal,⁵ provided that the recipient had been able to anticipate the future receipt, as we have argued. This should be true irrespective of the actual value of the marginal propensity to consume permanent income. Since these coefficients appear to differ significantly from each other, this result does not seem consistent with a permanent income framework.

In sum, I do not wish to deny that Landsberger's explanation has some relevance or to imply that the disposition of windfalls is unlikely to vary, depending upon the (relative) magnitude of these windfalls. I still suspect, however, that institutional conditions may have played a larger role in producing the divergent sets of results than Landsberger believes. This suspicion is strengthened by the fact that, for the selected sample of veterans who received NSLI dividend payments in 1950, there is no evidence of a declining marginal propensity to consume this windfall. In any event, Landsberger's results do not constitute a particularly strong confirmation of Friedman's permanent income hypothesis; in this respect, at least, his work appears to supplement, rather than contradict, the findings of [1] and [2].

RONALD G. BODKIN*

⁴ There would seem to be only two ways in which a permanent income theorist could logically argue that this effect (increased immediate consumption) would not occur. One of these would be the case in which news of the payment and its actual receipt coincided, which was certainly not the case with the restitution payments, as these were generally the subject of lengthy negotiations. Secondly, the recipient could have taken an "I'll believe it when I see it" attitude. However for the 1957-58 survey year examined by Landsberger, this attitude could hardly have been widespread, as individuals scheduled to receive restitution payments in the 1958-59 survey year could observe that other individuals in the community were already receiving restitution payments from the German government.

⁵ Actually, the predicted values of these two coefficients would be in the ratio of $1:1+r$, where r is the subjective rate of discount of the "typical" household of the society. Since r has been estimated to lie in the range between one-third (U. S. data) and one-fifth (Israeli data), the ratio between the predicted values of the coefficients would be between 3:4 and 5:6. The discrepancy between Landsberger's estimated coefficients still appears to be statistically significant, according to this interpretation, which is based upon the permanent income hypothesis.

* The author, who is associate professor of economics at the University of Western Ontario, wishes to thank Roger C. Bird for his very helpful comments without committing him to any errors of fact or analysis which may be present in this reply.

International Factor Costs and Factor Use: Comment

In an excellent review article [2] Leontief questions the usefulness of the Minhas factor reversal study [4] because Minhas' estimates of the elasticity of substitution are very close to one, for it is well known that factor reversals cannot occur in a Cobb-Douglas world. Leontief alleges that likely errors in measuring the wage rate lead to a downward bias in the least-squares estimates of the elasticity of substitution. He therefore concludes that the true values are unity, which implies that we are in a Cobb-Douglas world and the recent work on the generalized constant elasticity of substitution production function is of questionable usefulness. Using a common errors in variables framework, this note will show that the bias is towards, and not away from, unity as Leontief suggests.

Leontief says:

Interested in demonstrating the practical importance of crossovers, he [Minhas] naturally rejected the Cobb-Douglas function . . . and reached out for a formula capable of showing their existence. . . . This suggestion would appear to be even more plausible if in applying the least-squares method to estimate the slopes, b_i [which are the estimates of the elasticity of substitution] in the log linear equation . . . $[\log(V/L)_{ij} = \log a_i + b_i \log w_{ij}]$,¹ Minhas had not proceeded on the assumption that only the variable $(V/L)_i$ is subject to random errors, while the variable w_i is not. Had he instead, in fitting the slopes of these regression lines, allowed also for errors affecting the observed magnitudes of w_i , all estimated elasticities would necessarily turn out to be larger, since in 23 out of the 24 industries examined by him, the magnitudes of the b_i 's . . . turn out to be less—although in most instances only slightly less—than 1. This means that their values would be still closer to 1—the constant elasticity of the Cobb-Douglas function [2, p. 343].

In order to understand Leontief's error, first consider the method used for measuring the wage rate.² It is measured by dividing a given industry's

¹ $(V/L)_{ij}$ is the value added-labor ratio for industry i in country j , and w_{ij} is the wage ratio of industry i in country j .

² This analysis is a modification of Lucas [3, pp. 26-30].

total wage bill by the number of man-hours employed by that industry, i.e., $w_{ij} = W_{ij}/L_{ij}$; where W_{ij} is industry i 's total wage bill. Since W_{ij} comes from accounting records, it can reasonably be assumed to be measured without error. Therefore, the error must be in the measurement of L_{ij} . The recorded number of man-hours is correct, but the quality of labor is probably heterogeneous over the sample. In other words, an hour of labor services in one part of the world is not the same commodity as an hour of labor services in another part of the world.

To find the bias arising from this type of error, suppose that L_{ij} , the measured labor input, is only a portion of the true (quality-corrected) labor input. Let $L_{ij} = L_{ij}^*/u_{ij}$, where L_{ij}^* is the true value and u_{ij} the error.

If the true wage rate is w_{ij}^* , it will equal

$$\frac{W_{ij}}{L_{ij}^*} = \frac{W_{ij}}{L_{ij}} / u_{ij},$$

which implies that

$$\log w_{ij}^* = \log \frac{W_{ij}}{L_{ij}^*} - q_{ij} = x_{ij} - q_{ij} = x_{ij}^*,$$

where

$$q_{ij} = \log u_{ij}, \quad x_{ij} = \log W_{ij}/L_{ij} \quad \text{and} \quad x_{ij}^* = \log w_{ij}^*.$$

By the same reasoning, the true output-labor ratio can be shown to be

$$\frac{V_{ij}}{L_{ij}^*} = \left(\frac{V_{ij}}{L_{ij}} \right) \frac{1}{u_{ij}},$$

which implies that

$$\log \frac{V_{ij}}{L_{ij}^*} = \log \frac{V_{ij}}{L_{ij}} - q_{ij} = y_{ij} - q_{ij} = y_{ij}^*,$$

$$\text{where } y_{ij} = \log \frac{V_{ij}}{L_{ij}} \quad \text{and} \quad y_{ij}^* = \log \frac{V_{ij}}{L_{ij}^*}.$$

Given these considerations, the "true" specification for estimating σ_i would be

$$(1) \quad y_{ij} = a + \sigma_i x_{ij} + (1 - \sigma_i) q_{ij} + \eta_{ij}.$$

This, of course, means that the previous specification

$$(2) \quad y_{ij} = b + \delta_i x_{ij} + \epsilon_{ij}$$

is wrong (η_{ij} and ϵ_{ij} are the errors).

If σ , were estimated by least-squares with the commonly used (2) specification, the estimating equation would be³

$$(3) \quad S = \frac{\Sigma(x - \bar{x})(y - \bar{y})}{\Sigma(x - \bar{x})^2} = \frac{\Sigma(x - \bar{x})[\sigma x + (1 - \sigma)q - \sigma\bar{x} - (1 - \sigma)\bar{q}]}{\Sigma(x - \bar{x})^2} \\ = \sigma + (1 - \sigma) \frac{\Sigma(x - \bar{x})(q - \bar{q})}{\Sigma(x - \bar{x})^2}.$$

Since $x = x^* + q$ and $\bar{x} = \bar{x}^* + \bar{q}$,

$$(4) \quad \text{plim}(S) = \sigma + (1 - \sigma) \text{plim} \frac{\Sigma(x^* + q - \bar{x}^* - \bar{q})(q - \bar{q})}{\Sigma(x - \bar{x})^2} \\ = \sigma + (1 - \sigma) \frac{\text{Cov}(x^*q) + V(q)}{V(x)}.$$

If x^* and q are assumed to be independent (a reasonable assumption since x^* is nonstochastic), the bias will be

$$(5) \quad (1 - \sigma) \left[\frac{V(q)}{V(x)} \right],$$

which is positive for $\sigma < 1$ and zero for $\sigma = 1$. If, however, x^* and q are not independent, the bias will be

$$(5') \quad (1 - \sigma) \left[\frac{V(q)}{V(x)} + \frac{\text{Cov}(x^*q)}{V(x)} \right].$$

For a linear homogeneous production function x^* , the efficiency-corrected wage rate depends on the efficiency-corrected capital-labor ratio. If technical progress across countries is Hicks neutral (as Arrow, Chenery, Minhas, and Solow [1] suggest it to be), the efficiency-corrected capital-labor ratio is the same as the uncorrected ratio. Because the most efficient labor force is usually found in the countries with largest capital-labor ratios, we can expect a positive correlation between x^* and q (the quality index). Therefore, the covariance between x^* and q is positive, which only implies a stronger upward bias.⁴

Therefore, Leontief is incorrect about the direction of the bias due to errors in the variable w . Rather than expecting the true values of σ to be smaller than the estimated values, we would expect them to be larger. The existence of the bias does not detract from the usefulness of Minhas' work; it gives it, instead, greater significance.

BOOK REVIEWS

General Economics; Methodology

Economics: Analysis and Policy. By NORMAN F. KEISER. New York: John Wiley and Sons, Inc., 1965. Pp. xviii, 720. \$8.50.

The chief virtues of this recent entry in the textbook sweepstakes are its wide array of useful information, its effective use of historical and institutional material, its extensive documentation, and its ideological commitment. Its major faults are its inability to present economics as an engine of analysis, together with its graceless and pedestrian prose.

To detail accomplishments first, Professor Keiser's book presents a varied menu of recent and pertinent information on growth rates (e.g., Denison's study), corporate size and concentration, income distribution, union organization, and other staples of the elementary text. His discussion of federal, state, and local expenditures (Chap. 16) seems especially well done and his examination of "the methods of monopoly" (Chap. 25) offers a particularly helpful summary of the available information even though we need not accept his pronouncements (pp. 136, 586) about the prophetic significance of Berle and Means. As exemplified by the chapter on "cultural variations in the solution of basic economic problems" the author covers, though he does not always command, the territory of history and anthropology; among the many readings interspersed throughout the text is a hair-curling account of child labor in the mines and mills (on pp. 39-43 of that chapter) that shows the author's concern with the evils of industrial civilization.

As another entry on the positive side of the ledger, the footnote citations are far more extensive than the average elementary text and, at the cost of making the format more formidable, enhance the reference value of the book for both the ambitious student and the indolent instructor. Example: half a dozen items at page 508 dealing with changes in labor's share of the national dividend. A rough count of the index reveals from one to 14 citations apiece for about 360 authors—and 15 for Norman F. Keiser (plus 4 more that escaped the indexer).

On the debit side, the author plows through 150 pages of price theory—Chapters 3, 4, 17 through 21, and parts of 25—where his heart was clearly not in his work. The analysis is perfunctory, the exposition slipshod, the examples lifeless, and the significance for the rest of the book dubious. The relation between the firm's cost curves and the industry supply schedule is never properly explored. This unfortunate omission occurs because the author makes a horseback survey of the industry in Chapters 3 and 4, develops the marginal analysis of the competitive firm in 18 and 19, but neglects to return to the industry for the pick and shovel work that then becomes appropriate. Almost completely ignored is the determination of equilibrium for the economy as a whole. The instructor who uses this treatise for its institutional material and its

macroeconomic analysis ought to piece it out with a good paperback primer on price theory.

The style, while honest and unpretentious, appears graceless and garrulous. Consider this typical example where the second sentence with its pair of "one in which's" and its unbalanced ending indicates both careless writing and absent-minded editing. "The principle of diminishing returns is directly related to cost. Typically, the pattern for a firm is one in which (starting from zero production) the addition of more workers to a fixed amount of capital is one in which increasing marginal returns initially results, then diminishing and finally negative marginal returns set in. The addition of workers simply means that labor is now operating machines that were previously lying idle" (p. 426).

Since form and substance are inseparable, however, the author's expository problems arise from his conceptual difficulties. His failure to see and state that indivisibility of the fixed factor represents a necessary condition for increasing returns in the initial phase of the production function invites the tiresome stylistic maneuvers of the passage quoted above. Creating an elementary textbook is an exacting art form which ought not to be attempted by academicians who refuse to take their writing seriously.

The book has a clear and distinct point of view which emerges in the populist rhetoric that spices up its bread and butter style when the author turns his attention to the "scandalous practices" of corporations (p. 130), the "neurotic drive to please their superiors" on the part of corporate executives (p. 136), "the mansions of the wealthy" that escape their fair share of property taxes (p. 395), our "basically probusiness and antilabor" ideology (p. 522), and "the infamous Nate Shefferman, union buster par excellence" (p. 547). Since Samuelson has become a man for all seasons, this new text which speaks for the winter of our discontent offers a special commodity for a particular sector of the market.

*Claremont Men's College and
Claremont Graduate School*

Basic Economic Principles. By ROBERT A. LYNN. New York: McGraw-Hill Book Co., 1965. Pp. viii, 428. \$6.75.

According to the book jacket, this text is designed to be used for a "one-semester introductory course at the beginning undergraduate level." The premise behind *Basic Economic Principles* seems to be that existing texts are too difficult but not too comprehensive for this purpose. It is possible to simplify by greatly restricting the number of concepts or ideas the student is asked to comprehend and then working over this restricted list thoroughly. Robert Lynn, however, has attempted to retain the broad coverage of the typical elementary text while reducing the complexity of the included analytical material. To quote the book jacket once more, "Freshmen and sophomores using this text can be introduced to macro- and micro-economics without wading through a sea of language and symbol." Unfortunately, in avoiding the sea they will end up in a bog.

To retain comprehensive coverage while keeping the analysis "simple," Lynn is forced to give only the most cursory treatment to many important topics. To avoid taxing the student's ability to follow a logical chain of reasoning or to grasp abstractions, familiar concepts are reworded or stated in a nonrigorous fashion, e.g. "Because of ability to pay, diminishing utility, and substitution, we have seen that a price cut can produce a stretch in the quantity demanded. The amount of this stretch is called the *elasticity* of demand" (p. 225). Even the style of writing suffers from the attempt to "water-down" economic analysis to the level presumed digestable by beginning college students.

The text is divided into eight parts which are further subdivided into chapters. After the usual introductory material, Lynn takes up national income analysis and the monetary system, international economics, supply and demand, competitive and monopolistic markets, and factor pricing in that order. The book concludes with a discussion of current economic problems and a glossary of key concepts.

The several parts of the text vary greatly in merit. The early chapters on business and labor organizations are well done, but the sections following, on national income determination and the monetary system, are very weak. Lynn presents the usual conclusions from the simple income model without presenting anything resembling the model, and the student pursuing "why" questions is bound to become confused. Except for a good exposition of the deposit-creation process, his treatment of the monetary system is so brief as to be misleading. Both these sections and the following discussion of international economics suffer from the fact the student has not yet been introduced to the concepts of supply and demand. However, once these concepts have been introduced, things improve materially. The treatment of competitive markets and the various degrees of monopoly is fully satisfactory at the intended level, providing a balanced evaluation of the issues and many useful insights into practical problems. But for a confused analysis of interest rate determination, the discussion of factor pricing would be of the same quality. Certainly the strength of this text lies in the sections concerned with microeconomics. This strength results from the use of the usual graphs and analytical tools of price theory. The presentation is at once both more precise and more easily understood. However, it does not differentiate Lynn's product.

The teaching devices (summary, learning key, questions for review and discussion) at the end of the chapters emphasize definitions and memory work rather than applications of the analysis. They might be appropriate for secondary school students but could be seriously questioned for use at the college level. For example, the learning key consists of a "fill-in-the-blanks" question set for which the first two letters of the correct word are provided. Similarly, one might question the complete lack of suggested follow-up or supplementary reading and the almost complete absence of supporting footnotes for the many factual statements in the text. There are numerous graphs but often they are not discussed in the text. Interested students deserve better!

A conscientious reviewer would have to note many other differences with the statements made, the definitions used, and the space allotted to various topics in *Basic Economic Principles*. In particular, the definitions of terms or

concepts in the text and glossary may surprise many economists (e.g., "Assets and Liabilities are always equal and thus balance," p. 387). However, the difficulties Lynn has all seem to stem from the attempt to bring economic theory down to some assumed "understandable" level—a difficult task under the best of circumstances.

Only those readers who share Lynn's appraisal of the need for a "watered-down" version of the standard elementary text are likely to find his book useful. They will have to take care, especially in the macroeconomic section, in building on the blocks provided, but all the topics are there for a starter. Others, sharing the reviewer's opinion that a more restricted, more intensive approach will offer greater classroom dividends, will find selecting assignments from existing texts designed for the usual two-semester sequence better suited to their purposes than the book under review.

BURNHAM O. CAMPBELL

University of California, Los Angeles

**Price and Allocation Theory; Income and Employment Theory;
Related Empirical Studies; History of Economic Thought**

Modern Capital Theory. By DONALD DEWEY. New York: Columbia University Press, 1965. Pp. x, 238. \$6.50.

The object of this book is to present an intelligible but rigorous restatement of the theory of capital. Professor Dewey serves clear warning that he is concerned only with the real theory of capital; he is not interested in "the monetary superstructure of capital theory that began in the 1920's, reached staggering proportions in the 1930's and 1940's, and still warps the teaching of economics in many places" (p.v.). His is the theory of Irving Fisher, in which capital productivity and the "taste" for investment jointly determine the marginal productivity of investment, the rates of interest on loan contracts, the rate of capital accumulation, the rate of income growth, the value of capital assets, and the division of income between investment and consumption.

Dewey concentrates almost exclusively upon the fundamentals of capital theory and clings "tenaciously to the truth that every proposition about income is also a proposition about capital and, conversely, that every proposition about capital is a proposition about income." This is truly the world of Fisher and Knight, and not the least of Dewey's contributions is to untangle some of the latter's cumbersome prose. There is but one factor of production, namely capital, which is defined as *anything* that yields a flow of services over time. Thus income is the surplus of services obtained over those necessary to maintain. If this reminds the reader of Knight's remarkable piece of vegetation, the Crusonia plant, it should. Indeed, the Crusonia model is the heart of the book.

Dewey achieves a great deal with the Crusonia model; to me, more than Knight did. He discusses Knight's case, constant returns to investment. But he introduces the case of diminishing returns as well by distinguishing between "live" Crusonia, which reproduces, and "dead" Crusonia, which can only be consumed. In the latter case, the real capital stock and the value of

the capital stock differ because a unit of live Crusonia must exchange for more than one unit of dead Crusonia. The system must have a *numéraire*; and one must distinguish between the rate of interest (marginal productivity of investment) and the natural rate of growth of the real capital stock.

Given the model and the framework of discussion, the object of the book is achieved with clarity and simplicity. The framework is established in Chapters 1-3 and the basic elements of the model are presented in Chapters 4-5. Chapter 6, a bare fourteen pages, contains an analysis of equilibrium in capital theory; and it is a classic piece of exposition. By means of two simple graphs, Dewey explains all the fundamentals of capital theory. Chapter 7 contains a more detailed discussion of returns to investment, while Chapters 10-11 are devoted to the roles of risk and money in the theory of interest. Finally, in Chapter 12 Dewey clearly and logically disposes of some capital curiosa that have persisted for many years.

Ignoring a few trivial or nuisance errors, this book is subject to criticism along two lines. The first involves an error of commission. More specifically, the professional reader should skip, and the student be absolutely forbidden to read, Chapters 8-9. Chapter 8 contains a discussion of the theories of production and distribution in a two-factor model; but one factor (land) is absolutely fixed. In Chapter 9 a two-variable input model, with a Cobb-Douglas function in which both coefficients are one-half, is presented. Nothing is gained in either chapter; and unless one keeps Dewey's *basic* model in mind, a good deal may be lost through misunderstanding.

The second criticism concerns a matter of omission; hence it may not be a valid criticism at all. Nonetheless, the book is entitled *modern* capital theory; and the author specifically states that he has fashioned a complete theory of capital "from the materials willed to us by our predecessors from Thomas Aquinas to Robert Solow. . . ." To an extent this is true; one sees the names of Samuelson and Solow, Ramsey and Robinson, and even others. But more fundamentally, the Crusonia model cannot capture the essence of the recent advances in capital theory. Perhaps this is just to say that Dewey has concentrated upon the fundamentals of capital theory. Yet whichever side of the Atlantic one prefers, one is likely to believe that there have been fundamental developments in *modern* capital theory since the time of Fisher.

C. E. FERGUSON

Duke University

Economic Growth and Structure: Selected Essays. By SIMON KUZNETS. New York: W. W. Norton & Co., 1965. Pp. viii, 378. \$7.50.

This book consists of twelve reprinted essays on economic growth from Kuznets' cautious and independent pen. The essays carefully underline the precariousness of the basic data from which they grow, and they are careful in stating what is not known; they are often speculative and suggestive. The central interest lies in the generalizations, rather than in the data—in contrast with the nine statistical papers Kuznets has published in *Economic Development and Cultural Change*.

Five of the essays are on growth theory, population changes, and their recent patterns; three on industrialization, the takeoff doctrine, and agriculture; two on inequality and growth; and two on U.S. growth and its long cycles. They were published originally from 1954 to 1964 in various places, ten in English, two previously only in French.

Many of Kuznets' contributions have become standard items in the literature of growth. Over a span of ten years, it is likely one would sometimes change his mind. Kuznets recants on only two matters. One of them is that he is not so sure now as in 1954 that retardation of per capita income growth rates is "observable and immanent" (pp. 20-23).

He is doubtful about the usefulness of current explicit theories of economic growth. He even stated (in 1955) that no "significant theoretical work" on the theory of economic growth broadly defined has been done in the hundred years since the mid-nineteenth century (pp. 4, 5), except for attempts to revive Marxist theory. I would argue in partial contrast that major progress has been achieved in the past 15 years which need not give place to anything done in the nineteenth century.

Economics as such is downgraded in the Kuznets vision of economic growth. He accepts what has come to be orthodox: "The transformation of an underdeveloped into a developed country is not merely the mechanical addition of a stock of physical capital; it is a thoroughgoing revolution in the patterns of life and a cardinal change in the relative power and position of various groups in the population" (p. 30).

Accumulation of "empirical and tested knowledge" is seen as the true basis of production and population growth during the past two centuries (p. 60), and so there is a central need for a theory of the production of knowledge. Most theories of growth underemphasize political and social institutions; only oversimplification yields determinant answers (pp. 69, 79). Free formulations and reformulations of testable theories accumulate perceptions and undermine dogmatic theories that claim universal validity (p. 81).

The application within nations of the growing international stock of useful knowledge is most unequal, due largely to "differences in historical background and antecedents" (p. 114). The use of force in international relations in the long run accelerates this spread of modern economic growth (pp. 116-18)—but the apparently inconsistent theorem is also presented that major wars depress growth in participating countries (pp. 54-57). Population growth has both positive and negative effects on income growth, the latter mainly relevant to low-income countries (pp. 137 ff.). The physical misery of the world's poor is diminishing, as their per capita incomes increase a bit; but their "political misery," the tension created by consciously falling farther behind the rising income levels of the high-income countries and by consciously greater technical lag, has increased (p. 174). Per capita incomes in present low-income countries are "much lower" than those of the present developed countries (save Japan) just before they began to industrialize (above \$200 in 1952-54 prices, as compared with below \$100 now in much of Africa and Asia) (pp. 117-18, 257-87). Underdeveloped countries have had

"entirely different beginnings" from those of present high-income countries (with qualification for Japan), and there are disadvantages, as well as advantages, accruing from a late start (pp. 176-93).

In a closed economy increasing productivity in agriculture is a requisite for industrialization; and desirable, despite the example of England in the nineteenth century, in an open economy. Growing efficiency in transport, communication, and warehousing is also crucial (pp. 197-99).

Rostow's takeoff concept is put through the Kuznets mill: it comes out discredited on statistical and logical grounds (pp. 213-25). In a number of countries, the ratio of net domestic capital formation to income was substantially higher than Rostow's "say 5 per cent or less" at the beginning of takeoff periods; and in no case among 12 countries does the ratio approach double its initial size during dated "takeoffs." "I can only conclude that the available evidence lends no support to his suggestions" (p. 227). There are other objections (p. 232), both to the sequence of stages and to the notion of a distinct takeoff stage.

On size distribution of income, Kuznets finds from scanty evidence somewhat greater inequality in less developed countries than in high-income ones. As growth occurs, dynamic changes check and in fact reverse the trends toward greater concentration resulting from cumulating past savings.

U.S. history combines a retardation in population and work-force growth, with acceleration in growth per capita and per worker. Three long swings in population and related variables are conspicuous in U.S. data since 1870.

The kind of inquiry here presented—induction from statistical and historical materials over a long period and many areas, leading by both cautious and imaginative reasoning to economic-social-political generalizing—seems a thoroughly fruitful approach toward understanding economic growth. These essays are most significant, not for the questions they answer, but for their purpose "to pose questions and advance suggestions." The data, when properly examined, says Kuznets, "always reveal findings that call for explanations that are not at hand."

THEODORE MORGAN

University of Wisconsin

Theory of the Firm: Resource Allocation in a Market Economy. By KALMAN J. COHEN AND RICHARD M. CYERT. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1965. Pp. xx, 406. \$7.95.

This book is an important addition to the rapidly growing stock of intermediate price-theory texts. It is a careful and comprehensive exposition, showing clear evidence of careful thought and hard work on the part of the authors.

Despite its title, the book covers all the major topics in price theory. In addition to extensive treatment of the firm, there are chapters on consumer demand, market equilibrium, general equilibrium analysis, and welfare economics. The authors' primary interest, however, is clearly the firm, and they give more weight to that subject than is common in price-theory texts. Indeed, chapters on other subjects give the impression of being more routine and me-

chanical than those on the firm. The chapter on general equilibrium, for example, hardly gets beyond matters of notation and the counting of equations and unknowns.

Part II, which is the core of the book, contains chapters on all the standard topics in the theory of the firm. Six chapters on competitive markets are followed by chapters on monopoly, monopolistic competition, duopoly and oligopoly, and imperfections in factor markets. The authors' negative appraisal (in my opinion justified) of the value of Chamberlin's model of monopolistic competition makes one wonder why they include a whole chapter on the subject in an already large book. The chapter on duopoly and oligopoly is especially well done and sets the stage for Part III of the text, "New Approaches to the Theory of the Firm."

The first chapter in Part III is an excellent one on decision-making in uncertain situations. There follow two chapters on "behavioral" theories of the firm. These chapters borrow heavily from well-known research on the subject by the authors and others at Carnegie Institute of Technology. Here, the going will be pretty heavy, at least for students not raised in the Carnegie tradition.

This is a long book. I find it hard to believe that many sophomores could fight their way through it in one semester. It is also a difficult book. Calculus is used freely, including partial derivatives, integration, and constrained maxima. Clearly, no one should adopt this text for students who have not had a good year-course in calculus. Even then, many students will need special help in places.

Two final comments: First, empirical material is used to illustrate almost every major theoretical topic. This is an important improvement over almost all existing texts. Nevertheless, the empirical sections give the impression of having been tacked on for the most part. We have yet to see the first price-theory text that will show how good theory and careful quantitative analysis can be used to illuminate the real world. Second, a word on the choice of topics. It is useful to have the material on behavioral approaches available in textbook form. But in a text written at Carnegie, it would also be nice to have some material on managerial economics. Chapters on programming and inventory theory would be natural candidates. My own preference would have been for a chapter on at least one of these topics instead of the second chapter on behavioral models.

EDWIN S. MILLS

The Johns Hopkins University

An Introduction to Microeconomic Theory. By WILLIAM I. DAVISSON AND JOHN G. RANLETT. New York: Harcourt, Brace & World, Inc., 1965. Pp. vii, 226. Paper, \$2.45.

The authors of *An Introduction to Microeconomic Theory* had as their purpose in writing this text the development of "an approach to microeconomic theory that would be uniquely adapted to the introductory course in economics."

The text is divided into three parts. Part I, entitled "The Purpose and

Method of Microeconomics," defines microeconomics, outlines "the theoretical approach," and discusses briefly the basic concepts of price theory. In Part II, "The Tools of Analysis"—encompassing production theory, costs of production, and the theory of demand—are explained at some length. Finally, in Part III, "Market Structures," the authors detail the market characteristics of perfect competition, monopoly, and oligopoly; describe specific industry examples of each of these three market structures; and examine the theory of these three structures, as well as that of monopolistic competition. The last chapter in Part III is devoted to a consideration of the allocation of resources and the distribution of income. The book also contains a glossary of the economic terms used by the authors.

The authors have done a workmanlike job of presenting the essence of product pricing theory. The question arises, though, as to whether theory coverage which is little more than essence alone is sufficient for an introductory text. At the principles level, it may be argued that the maximum amount of elaboration and illustration consistent with the time span available for the coverage of the principles course is desirable. Further, only one chapter is devoted to factor pricing. The theoretical portion of this particular chapter is limited to a consideration of the functional distribution of income as explained by the marginal productivity theory.

A step forward in the authoring of introductory texts is accomplished by the omission of such topics as the history of American labor unions and the structure of business organization. Valuable though information about subject areas such as these is, the classroom coverage of them often means that the theory itself is covered in less depth. The graphical presentation used by William Davisson and John Ranlett is in black and white only, but it should be singled out for its clarity and usefulness as a complement to the verbal portion of the theoretical analysis.

In the Preface, the authors state "that there is a need for an elementary text that can provide an analysis of actual market situations as well as an explanation of the premises on which the logic of microeconomic theory is based. Too often the beginning student is left with the feeling that although economic theory may be interesting it has relatively little to do with practical aspects of the economic society in which we live. With this in mind we have designed this text specifically to demonstrate the meaningful relationships between microeconomic theory and the practical realities of the American business world." The approach used to interrelate the theoretical and the real is the presentation of separate "market structure" chapters for perfect competition, monopoly, and oligopoly in which the market characteristics of each of their market structures are outlined; then, a specific industry, such as trucking for perfect competition, is described for the purpose of illustrating each of the market structures under consideration. Each of the market-structure chapters is followed by a "market theory" chapter in which perfect competition, monopoly, and imperfect competition (encompassing both oligopoly and monopolistic competition) are examined in theoretical terms.

Swayed by his own biases and preconceptions, one may question the value of such a "design" for the principles course. In any case, it seems that the au-

thors have devoted far too much space, at least relatively speaking, to the description of the specific industries which are used to illustrate the market structures. Approximately one-fifth of *An Introduction to Microeconomic Theory* is directed to a consideration of such things as the historical development and recent production statistics of these industries. Generally speaking, this descriptive material does not go as far in providing the desired link between theory and reality as would have been provided by an examination of such practical matters as price and output determination in the industries under consideration. Furthermore, it seems as if it would have been more logical to present the theory chapters before, rather than after, the structure chapters.

A final point, which in no way is intended as a criticism of the contents of *An Introduction to Microeconomic Theory*, relates to the practical consideration of the present or future availability of a macroeconomic theory counterpart to the book under review. Those selecting texts for two-term principles courses no doubt would make the availability of such a counterpart one of the several criteria to be used in the selection process if they were considering the adoption of *An Introduction to Microeconomic Theory*.

RICHARD E. NEEL

University of South Florida

Theory of Economic Statics. By MICHAEL J. BRENNAN. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1965. Pp. 535. \$8.95.

As the fundamental purpose of this book, Michael Brennan sets out to stress the use of theory as a tool of analysis and to avoid having the students come away with a knowledge of the "buzz words and the fragments" but no knowledge of "how they fit together." I am entirely in sympathy with this purpose and would certainly strongly recommend any intermediate theory book which accomplishes this feat. Unfortunately, the set of all such intermediate theory books remains empty. This is not a condemnation of Brennan, since he has written an intermediate theory book that is of the first rank in its coverage of the material and is among the best in readability.

The book itself is a bit unusual in that it includes 20 chapters on microeconomics and then has a nine-chapter section on macroeconomics. In addition, he has included a three-chapter section on the how, what, and why of economics: the first two chapters essentially contain a discussion paralleling Knight's, *The Economic Organization*, and the last contains a brief introduction into methodology. His treatment of consumer demand theory appears to be the standard treatment of a text at this level, except that no consideration is given to the classical utility approach (cardinal utility). On this point I have a feeling that many economists seem to believe that because cardinality of utility is not necessary to derive the theorems of demand theory it cannot exist. Or put differently, because a given set of demand functions for an individual consumer is not integrable into a unique utility function does not imply that the consumer cannot possess a unique utility function. In spite of this omission the discussion is very complete and assumes little or no prior knowledge on the part of the student. This is a distinct advantage, since

many students either have understood little about economics from their principles courses or have forgotten what little they did understand.

The production side is again handled in the standard way and again a very thorough and well-written job is done. The treatment of supply functions is adequate but certainly no better than, say, Leftwich. The discussion of long-run equilibrium for monopoly (as in all other texts at this level that I am familiar with) handles the scale problem in a peculiar fashion. The point is made that a monopolist may not operate an optimum-scale plant (by this is meant that he may not operate at the minimum point on his long-run average cost curve) and that a competitive firm would, and thus the implication is given that monopoly may be inefficient for this reason. However, since the monopolist is the industry, any comparison of his position of long-run equilibrium must be made with respect to the long-run equilibrium of a competitive industry and not a competitive firm. Since there is no presumption that a competitive industry will operate at the minimum point on its long-run average cost curve, this should not be required of the monopolist.

Brennan's book offers more than the usual intermediate text on the problem of the pricing of resources. In addition, he has a fine chapter on applications of the theory of resource pricing that should stimulate thinking and discussion on the part of the students. As pointed out above, the final part of the book contains a discussion of macroeconomic theory where the distinguishing characteristic is that it is a clear, concise statement of the level of macroeconomics usually contained in intermediate textbooks. I'm not sure why this macro section is included, since the book contains much too much material for a one-semester course covering both microeconomics and macroeconomics, and for a strictly macro course this section is too brief to be used as a text.

In conclusion, this is a very well-written book with quite extensive coverage of the microeconomic material. Some people might prefer a more mathematical treatment (Brennan relegates almost all mathematics to a brief mathematical appendix at the close of the book). However, for those who feel that understanding of economic theory is more likely to occur from a combination of verbal exposition and graphical manipulation, this book will be very adequate.

THOMAS R. SAVING

Michigan State University

Price Theory in a Changing Economy. By HENRY GRAYSON. New York: Macmillan Co.; London: Collier-Macmillan, Ltd., 1965. Pp. xxi, 247. \$5.95.

It was said of the Bourbons at their restoration to the French throne after the Revolution that they had remembered everything and learned nothing. This micro-theory textbook, aimed, its preface claims, at both the graduate and undergraduate market, mentions everything and teaches nothing. This is its major, although by no means only, flaw, and we shall deal with it first.

There is frequently no apparent connection between the formulas and graphs on the one hand, and the text on the other. In the very first technical discussion in the book, a formula is given for arc elasticity which is totally unexplained (p. 7). Not even the notation in the formula is defined. Someone who has been through it all many times and who has some confidence in his

ability in manipulating formulas may guess what the symbols mean and work back to find the connection between the formula and the words, but students will probably be encouraged by the author's tactics to take the formula on faith and memorize it. This is not an isolated case. Some of the graphs are explained in so cursory a fashion that it is impossible to follow the discussion, where there is one.

The book abounds in absurdities and infelicities such as, "When elasticity of supply is under discussion, we always assume that the supply curve slopes up and to the right. Otherwise, measurement of elasticity would be meaningless" (pp. 7-8).

Pseudo-empirical observations of doubtful validity, which supposedly illustrate the theory, present a divertissement from the innumerable diagrams. A short discussion of the cobweb theorem notes that when the supply is elastic relative to the demand, the equilibrium is unstable and the oscillations grow in magnitude. Since the supply of agricultural products is inelastic and that of industrial products elastic, our author goes on to say, "Consequently, in an industrial economy we may expect to find a considerable measure of instability and a tendency toward change, whereas in an agrarian economy static conditions will be more likely to predominate" (p. 12). The usual thought on these matters is that the cobweb analysis applies almost exclusively to agriculture, where lags are long, rather than to manufacturing. The author seems to be confusing the alternative of damped versus explosive price and quantity fluctuations, which is what the cobweb theorem is about, with the alternative of growth versus stagnation where a more complex analysis seems to be called for.

One of the real curiosities in the book is the section entitled "Cybernetics and Automation" which appears in the chapter on the theory of wages. The author claims we have a structural unemployment problem, with a shortage of jobs for the less skilled and a shortage of workers for the more skilled jobs. The situation is ominous; since "By far the larger proportion of the labor force is composed of individuals who through hereditary or environmental limitations, or both, are not amenable to the training or retraining necessary to equip them with the kinds of skills needed. Rather we are faced with the prospect of a comparatively small elite group . . . for whom the demand in the labor market is likely to exceed the supply, and a majority group who will not meet most of the job requirements for whom the demand in the labor market will fall far short of the supply" (p. 185). The author asserts that the "remarkable" changes that are bringing this situation about "do not lend themselves to ordinary price-theory analysis," but he does not attempt to develop an extraordinary analysis of his own to deal with them. He is probably right to refrain.

Although it is difficult to cite any portion of this almost uniformly bad book as the worst, a strong candidate is the Part on the subject of distribution. In its 33 pages are found four chapters including the chapter on wages containing the discussion of unemployment referred to above. But surely the gem of this Part is the 6-page chapter entitled "Capital and Investment Theory." None of the 11 sections into which this 6-page chapter is divided contains

anything about the productivity of roundaboutness, time preference, trees being cut down, or kegs of wine aging. Instead we have three paragraphs on liquidity preference, which apparently disposes of the matter of the rate of interest.

The author acknowledges the help of 14 colleagues. They should sue.

BARBARA R. BERGMANN

University of Maryland

Francis Hutcheson and David Hume as Predecessors of Adam Smith. By W. L. TAYLOR. Durham, N.C.: Duke University Press, 1965. Pp. viii, 180. \$6.00.

This volume is a study of relationships among the economic ideas of three of the chief figures in eighteenth-century moral philosophy. Part I is an expansion of Taylor's 1956 article which appeared in the *South African Journal of Economics*. It is concerned for the most part with showing the nature of the personal and intellectual relationships existing among Hutcheson, Hume, and Smith. While it does not present any facts not previously known to the student of the period, the focus of this study and the manner of presentation provide sufficient novelty to hold the interest of the reader, whether he be thoroughly familiar with the original sources or not.

Part II, which is entitled "Economic Commentaries," attempts a task which is beset with pitfalls, i.e., to establish the influence of specific ideas or doctrines of Hutcheson and Hume upon Adam Smith. In some, a minority, of these cases, the reader may well feel that the author has failed to make his case. The first chapter of Part II, for example, attempts to show that Smith's view of the division of labor was strongly influenced by the teachings of Francis Hutcheson. There is, however, nothing in the text or the many quotations from Hutcheson which indicate that Hutcheson's ideas on the division of labor were substantially more advanced than those of Aristotle or Xenophon. This being the case, perhaps the most that we can really say is that Hutcheson may have been responsible for introducing Smith to the ideas of the Greek philosophers on this subject.

The second chapter of Part II, "Notions on Value," on the other hand, is full of interest to the historian of economic thought. Hutcheson is shown to have had as good a conception of the joint roles of utility and cost in the determination of value as was possible prior to the development of the marginal concept. Further, it is shown that Smith followed along Hutchesonian lines in his *Lectures* of 1763 but for some inexplicable reasons, perhaps the influence of David Hume, put the greatest emphasis on cost of production in the *Wealth of Nations*.

Of the remaining chapters, those on money and interest, luxury, trade, and taxation hold for the reader much the same interest and stimulation afforded by Chapter 2. The only chapter which falls substantially below this level is "The Theory of Property." Here it is not so much Taylor's treatment as the lack of anything to be treated that makes the chapter sag. Smith's remarks on the subject are so few and so generally in keeping with those of his age that any attempt to ascribe a definite ancestry to them must necessarily be rather unconvincing.

One of the more interesting facts brought to light by Taylor's study is that

Smith did occasionally exercise rather poor judgment in his borrowing of ideas. His choice of Hume's emphasis on labor as the source of value rather than Hutcheson's balanced emphasis on utility and scarcity and his decision to follow Hutcheson's rather pedestrian approach to questions of money and interest rather than Hume's brilliant treatment being cases in point.

Taking both the strong and the weak points of this study into consideration, one is bound to conclude that the strong far outbalance the weak and that it is an essential piece of reading for anyone who aspires to an understanding of the development of economic thought in the eighteenth century.

Economic History; Economic Development; National Economies

The Vital Few: American Economic Progress and Its Protagonists. By JONATHAN HUGHES. Boston: Houghton Mifflin Co., 1966. Pp. vi, 504. \$6.95.

Fowler, in the latest edition of his *Modern English Usage*, comes close to conceding defeat on "protagonist." Jonathan Hughes, with an assertive major title chosen, leaves his subtitle ambiguous. Are the eight entrepreneurs vividly portrayed in this book to be thought of as advocates of U.S. economic progress, or as "leading actors" in the drama, or perhaps as representing in their personalities and behavior some of the leading themes in the process? I suspect the last interpretation is correct, for Hughes explicitly says that he is using them as "surrogates," or substitutes, for the many other individuals who "did the same sorts of things in life" but whose biographies are inaccessible or less interesting. These eight men—William Penn, Brigham Young, Eli Whitney, Thomas Edison, Andrew Carnegie, Henry Ford, E. H. Harriman, and J. P. Morgan—are chosen because their acts exemplify kinds of behavior that Hughes considers important in determining the way the economy of the United States has developed.

Henry Ford, I feel sure, would not relish the idea of being cast as a stand-in for anyone else, and perhaps the same might be said of each of these inner-directed individualists. What does Hughes mean by calling them surrogates? What do they represent? Of what are they typical? Of what universe is this an efficient and informative sample?

Hughes's answer lies in a conceptual scheme which he describes alternatively as a set of "stages of history," "conceptual categories," or "basic economic functions." These are (i) idealism; (ii) invention; (iii) innovation; (iv) organization; and (v) stagnation and decline. I must confess that I find this confusing. The five categories do not seem to stand all on the same footing; they are certainly not mutually exclusive; and the list seems uncomfortably open-ended (does not pragmatism have as good a claim to inclusion as idealism?). To call them "stages" is certainly to invite misunderstanding, for Hughes explicitly admits that they are not chronological and that "the nation lives simultaneously in all these stages." As "basic economic functions" the first four carry more meaning, but "stagnation and decline" sticks out like a

sore thumb. Hughes, significantly, has no entrepreneurs to represent this final "stage."

The expository strategy which underlies this list of concepts is to create a framework "in which the role of the individual in the economic history of the United States may be illuminated by the study of the contributions of a few men." As a justification for Hughes's sampling procedure, this leaves the reader dissatisfied. What Hughes is really after is a classification of entrepreneurs in terms of personality types—specifically, in terms of particular skills or orientations that can be shown to have been economically significant. The fifth stage—stagnation and decline—does not fit this interpretation. Hughes's interest here is in bureaucracy, which is not necessarily the same thing. It would not have been too difficult to identify two entrepreneurs whose chief claim to fame has been their ability to use bureaucratic structures effectively, and I am surprised that Hughes gives us instead an interpretive essay on "the credentials society"—albeit a very stimulating one.

Hughes's attempt at system-building is, in my judgment, a very qualified success. His biographical chapters, on the other hand, are excellent. They show wide reading, careful research, a lively and curious mind—and above all they are not dull. This is economic and entrepreneurial biography at its best; not antiquarian, but infused by a keen awareness of the economic process at all levels. If they have a weakness, it lies in the author's tendency to take personality as given: we are told a great deal about how the personality acted on the environment, but less about the reverse reaction—what doing these things did to the man who did them. This might have been a harder book to read if Hughes had delved deeper into the psychological literature on personality, but on the other hand it might have acquired another dimension of insight.

Entrepreneurial history—some of the time—tended to analyze conspicuous entrepreneurs as deviants: people who introduced change by departing from established sanctioned modes of thought and action. Hughes's findings support this point of view, though he does not use the term. On the other hand, at a different level of analysis, these patterns of deviance were themselves a recurrent pattern in U.S. economic life. Hughes's eight men illustrate this dialectic between deviance in particular aspects of behavior and conformity to the more fundamental social norms of success, progress, and rationality. Herein lies much of the interest of a fascinating, if uneven, book.

HUGH G. J. AITKEN

Amherst College

Capital Exports and Growth among U.S. Regions. By J. THOMAS ROMANS. Middletown, Conn.: Wesleyan University Press, 1965. Pp. xvii, 230. \$9.50.

Dr. Romans has made a rather heroic attempt to obtain measures of income, gross investment, saving, government revenue and expenditure, and net exports for each of nine major regions of the Continental United States. The same variables are also measured for the individual states. His major purpose is to explain and analyze the sources of differential regional per capita growth

rates over the period 1929-57 by making use of data on capital flows largely confined to the years 1953 and 1957. The impact of the federal government's fiscal policies, together with private investments and transfer payments, on these interregional investment flows is assessed.

The main accounting concepts employed are described by the following identities:

$$(1) X = S + Tn - (I + G)$$

$$(2) X_d = S + Tn - (I + G) - D$$

where:

X = Private net exports

S = Saving

Tn = Net taxes

I = Gross investment

G = Government expenditures

D = Income received from foreign investment

X_d = Private net exports from domestically employed resources.

Romans uses (1) directly to compute net exports (capital flows) by estimating personal and business saving for each state, in contrast to Department of Commerce procedures which treat savings as a residual. Needless to say, very difficult allocation problems arise and many *ad hoc* procedures have to be devised for allocating business retained earnings, depreciation allowances, and investment expenditures to individual states or regions. The difference between X_d and X in interstate or interregional trade can be relatively much greater than corresponding variables in international trade, because of greater differences in property income receipts.

As long as the analysis is confined to comparisons among the nine highly aggregated regions, his attempts to link levels of per capita investment and net exports to per capita income growth are rather disappointing. Although he measures marked differences in investment per capita, these are not significantly related to the very large differences in per capita income growth (p. 45). He did find that per capita saving was positively related to the absolute level of income and the share of property income—a fact which is not too surprising. The absolute level of federal government expenditures per capita in each state is also positively related to per capita income. However, high-income states tend to pay more taxes than they receive in expenditures; but, even so, these deficits are not significantly related to per capita income growth.

When Romans disaggregates down to the state level, he usually finds stronger relationships. High-income states are net exporters of capital—particularly New England and the Mideast. Since there is a generally negative correlation between per capita income growth and the absolute level of income, it turns out that growth in per capita income is inversely related to capital exports. Nevertheless, he concludes that the degree to which differential growth rates can be “explained” by interstate net capital flows is minimal. There are other factors, such as the switch from agricultural to manufacturing employment in the poorer states, which are more important in causing the gradual

convergence of per capita state income. However, the growth in nonagricultural income per worker does tend to be much more dependent on the net importation of capital than does growth in per capita income.

In general, it is very difficult to delineate any single empirically testable theoretical model that is adequate for explaining his numerous empirical relationships. There is always the problem of identifying the direction of causation with some variables to be "explanatory" and others to be endogenous. For example, the influence of interstate capital flows on growth is small after one allows for the differences in absolute income levels. But differences in per capita income are not by themselves too helpful as explanatory variables. Can an equilibrium level of investment for each state be defined using some idea of factor proportions in a production function which has the same parameters (including technical change) for all states? Romans himself notes that using a simple Harrod-Domar-type growth model where saving—both within the state and via capital imports—plays a central role is at least superficially in conflict with export-based theories of regional development. Having exports generating income seems to conflict with the importation of capital via a trade-balance deficit. Although George Borts has recently shown that the two theories can be consistent with each other in certain circumstances, it is still difficult to know whether improved access to capital or better export prospects is the leading variable in explaining an abnormally high growth rate.

In summary, one can say that Romans has done a very useful job in presenting empirical comparisons and relationships among the states despite the numerous "identification" problems involved. Although the importance of net capital flows is still not completely clear, one should not forget that large gross capital flows may still be extremely important in promoting the efficient specialization of investment activity. The book itself, while interesting, could probably have been organized somewhat more tightly with less repetition.

RONALD I. MCKINNON

Stanford University

Problems in Economic Development—Proceedings of a Conference Held by the International Economic Association. Edited by E. A. G. ROBINSON. New York: St. Martin's Press; London: Macmillan and Co., Ltd., 1965. Pp. xxi, 626.

This volume contains the proceedings of the International Economic Association Congress on the Economics of Development held in 1962. It is not possible here to discuss individually all the 34 papers in this collection; all one can hope to do is to give a rapid review of the contents of the four main sections which make up the book.

Section I begins with a useful survey of the theories of economic growth in capitalist countries by G. Ranis, followed by two papers on economic development in socialist countries, the theoretical paper by W. Brus and K. Laski and the applied paper by K. Plotnikov. This is followed by papers on an assortment of topics: "Agriculture and Balanced Growth," by G. U. Papi; "Education, Research and Other Unidentified Factors in Growth," by I. Svernilson;

"Historical Experience of Economic Development," by H. J. Habakkuk; "International Aid," by G. Leduc; "The Role of Taxation in Economic Development" by N. Kaldor; "Inflation and Economic Growth," by D. Horowitz; and finally, "Determinants of Saving in Developed and Underdeveloped Countries," by H. S. Houthakker. It is interesting to have Habakkuk's historical approach and Houthakker's econometric approach in the same section. A reader familiar with the literature on the underdeveloped countries will not, however, find any strikingly new developments in this section. The papers on taxation and on inflation confine themselves too much to generalities and the paper on education, research, and economic development is too sketchy. Collectively, the papers do not add up to "The Determinants of Economic Progress," which is the title of this section.

Section II, "Industrialisation and Methods of Increasing Labour Productivity," starts with two solid papers on the trends of labor productivity in Western Europe, North America, and Japan by A. Madison and in the non-Western countries by W. Galenson and J. R. Ericksson. We next have J. Pajestka's paper, "Stages of Industrialisation and Labour Productivity," which stresses, unsurprisingly, the relation between labor productivity and capital accumulation. This is followed by two interesting papers, one by W. E. G. Salter developing the "embodied growth" approach contained in his book *Productivity and Technical Change* and the second by S. Tsuru suggesting that the confusion between "real" and "value" aspects has led to errors in measurement of the effects of technological progress on productivity. Lloyd G. Reynolds in his useful paper discusses the relation between wages and productivity in the underdeveloped countries, while K. G. J. C. Knowles and H. A. Turner discuss this theme in relation to Great Britain and other advanced countries. J. T. Dunlop's paper evaluating the factors affecting productivity is much too brief and general; and the same may be said of S. Carlson's paper on the contributions of management to productivity. The section concludes with a round table discussion of the problems of individual countries.

Section III, "Techniques and Problems of Development Planning," opens with two papers, one by J. Tinbergen, "Simple Devices for Development Planning," and one by H. B. Chenery, "Approaches to Development Planning." Those familiar with the previous works of Tinbergen and Chenery will find the same quality but no strikingly new developments in these papers. These papers at least try to deal with the problem of *development* planning of the underdeveloped countries mentioned in the section title. This cannot, however, be said of the papers in the rest of this section. These, although they may be regarded as valuable contributions to planning theory, have little connection with planning in the underdeveloped countries. Under this category are the papers by P. Masse on discretionary or formalized planning, three papers on regional planning by G. Sorokin, J. R. Boudeville, and E. A. Lisle, and finally a highly technical paper, "Behavioural and Technical Change in Economic Models," by Richard Stone and Alan Brown.

Section IV, "The Stabilisation of Primary Producing Economies," starts with W. A. Lewis's notable paper on economic development and world trade, arguing (a) that the current decline in the terms of trade of primary products

is the inevitable result of the abnormally favorable prices which these products have enjoyed since World War II; (b) that there is no reason to believe that the ratio of world trade to world production will decline in the long run; and (c) that the rate of economic growth of an underdeveloped country is a direct function of the rate at which its exports can be expanded where possibilities of import substitution and foreign deficits are limited. After this, there are two papers on the long-run terms of trade, the first by M. Dantwala, who takes a pessimistic view, and the second by H. M. A. Onitiri, which is a useful survey paper. Next, we have a paper on the Kondratieff Cycle by L. H. Dupriez. The section concludes with three papers by G. Blau on international commodity agreements, by D. Walker on marketing boards, and by H. Hymen on the international tin scheme. In contrast to the preceding papers, the last three papers have the merit of actually dealing with the problem of the stabilization of primary producing economies. But they are implicitly based on the assumption that primary exports are subject to a much larger degree of short-run fluctuations than manufactured exports and that therefore the underdeveloped countries generally suffer from a much higher degree of short-run export instability than the advanced countries. This basic assumption does not now appear to be as obvious and unquestionable as it used to be, in the light of recent studies by various writers such as J. D. Coppock and A. I. MacBean.

H. MYINT

London School of Economics

National Income and Capital Formation in Mainland China—An Examination of Official Statistics. By SHIGERU ISHIKAWA. Tokyo: Institute of Asian Economic Affairs, 1965. Pp. xvii, 206.

The Chinese Model—A Political, Economic and Social Survey. Edited by WERNER KLATT. New York: Oxford University Press; Hong Kong: Hong Kong University Press, 1965. Pp. xix, 233, iv. \$4.00.

The Economy of Communist China—An Introduction. By YUAN-LI WU. New York: Frederick A. Praeger, 1965. Pp. viii, 225. \$6.00.

Although the number of monographs on particular aspects of the Chinese economy has increased rapidly during the past few years, there have been few attempts to provide the nonspecialist with an over-all view in a single volume. Dr. Wu's study represents an attempt to fill this gap, as, in a broader sense, does the collection of essays edited by Mr. Klatt. Professor Ishikawa's analysis of national income and capital formation, although narrower in scope than the other two volumes, is a basic reference work for anyone wishing to introduce himself to Chinese Communist national income concepts and data, useful to specialist and nonspecialist alike.

Any study of the Mainland Chinese economy must, from the outset, face the question of the reliability and value of official data emanating from Peking. It would be difficult to discover two more widely differing approaches to this problem than those of Wu and Ishikawa. The latter has attempted to re-

construct Peking's own estimates, taking care at each step to properly define and use the official figures, filling in gaps with his own estimates only when no official data are available. More than any other work on China with which I am familiar, Ishikawa makes explicit and clear what is not known as well as what is.

The result of these efforts is a collection of data which present a picture of economic development in China as seen by Peking for the years 1952-59. Because little or no official data have appeared since that time, there is no way of obtaining a comparable picture for the years 1960-65. Ishikawa's work also serves to demonstrate the high degree of internal consistency between widely disparate kinds of official statistics, an important first step in any attempt to appraise their reliability.

Ishikawa, however, purposely avoids the issue of whether the underlying official data accurately reflect real trends in China's economy. At times he does evaluate his results in a way that would indicate that, for at least the years 1952-57, he feels the official figures are relatively reliable (e.g., p. 48), but he makes no real attempt to deal with such key problems as the validity of official crop output data. He also intentionally does not convert the official national income figures, compiled according to Marxian concepts, into a Western conceptual framework. The reader who wishes to use the figures for purposes of appraising the performance of the Chinese economy or for international comparisons must be prepared to make his own conversion and, more important, his own appraisal of the worth of the underlying data. Ishikawa's study, therefore, should be looked on not as a substitute for but as a complement to such other national income studies as the one by T. C. Liu and K. C. Yeh. As such, it is a significant addition to our knowledge of the Chinese economy.

In contrast to Ishikawa, Wu rejects a large portion of the official figures and substitutes his own estimates in their stead. He also attempts to give a quantitative picture of economic performance during the years 1960-63 when no official statistics were available. The estimates he derives are a combination of trends derived from official figures and statements, guesses made by observers in Hong Kong and Taipei, and a variety of other kinds of data. The problem with this approach is that even the specialist has difficulty determining what the results mean. It is one thing to establish that there are biases in the official figures, and quite another to substitute one's own estimates which must, by their nature, be based on only one of several plausible and often arbitrary assumptions.

Nor are Wu's results always even plausible. I know of no other economist, for example, who believes that grain output in China fell in 1958 (p. 146). In his conclusion (p. 203), to take another example, his estimate of the annual rate of decline in per capita consumption is reduced from -2.5 per cent to -0.75 per cent when the years 1961-62 are included. One would expect the opposite, particularly given an earlier statement by the author that "... it was consumption that suffered most" in the 1961 crisis (p. 158).

These difficulties with the estimates, however, mar Wu's analysis less than might be supposed, principally because he does not appear to have relied very

heavily on these figures in writing the text. Thus Table VII-3 properly interpreted would seem to lead to the conclusion that Chinese agriculture was moving clearly, relentlessly, and none too slowly toward disaster as early as 1952. But in the text Wu uses such statements as "That agricultural production lagged behind advances in the nonagricultural sectors during the First Five-Year Plan is beyond doubt" (p. 132).

The discussion is best where the data are the least controversial. Chapter 6 on the industrial sector and much of Chapter 9 on international trade and aid are particularly useful. Wu's discussion of industry makes a number of important points, not the least of which is that industrial development in China and Manchuria prior to 1949 was far from insignificant.

Wu's book is, of course, more than just an appraisal of changes in output and consumption. The book was designed for a course in comparative economic systems and as such includes a discussion of organization and planning in China as well. As a presentation of the formal structure of Chinese economic institutions and plan procedures, these chapters are useful and well organized. Analysts of China and other Soviet-type economies, however, have often pointed out the fundamental differences between the formal rules and the actual operation of the economy. Emphasis on the formal side leads Wu to exaggerate such things as the effect on resource allocation of China's failure to properly utilize interest charges on capital (pp. 57, 202). For much the same reason there is a tendency to explain Chinese policies as little more than carbon copies of similar Soviet moves (e.g., pp. 27, 74) when in fact the reasons for or intent behind the two countries' policies, however similar on the surface, were quite different.

None of these remarks should detract from the fact that Wu has done a useful service by pulling together so much material into a single small and readable volume.

In the collection of essays edited by Mr. Klatt, only four of twelve concern themselves with economics. The remainder deal with everything from the role of mass media in China to Peking's policies toward Tibet and Sinkiang. The volume was apparently designed primarily to be read by "leaders of developing countries" rather than by professional economists or China specialists.

The brevity of most of the essays, together with their vast scope, causes a number of them to be rather superficial. Klatt's own essay on Sino-Soviet economic relations is a worthwhile summary of the subject, but his noble attempt to cover all of China's agricultural policies and problems from the 1930's to the 1960's in eighteen short pages is somewhat less successful. Other essays, particularly that by Funnell on changes in social values, are too polemical in tone to be genuine scholarly contributions.

The best essay in the volume is that by A. M. Halpern on the way in which the revolutionary experiences of the Chinese Communist leadership have shaped their attitudes and goals in the area of foreign policy. Also well worth reading are Joseph Levenson's summary of Peking's policies toward the various religions within China's borders and C. T. Hu's presentation of the regime's efforts in the field of education.

It is unfair, however, to criticize a book for failing to meet an objective for which it was not designed. The limited usefulness of these essays for the professional economist results from the fact that the book was not written for him.

DWIGHT H. PERKINS

Harvard University

The Rate and Pattern of Industrial Growth in Communist China. By KANG CHAO. Ann Arbor: University of Michigan Press, 1965. Pp. viii, 188. \$6.75.

How fast has Communist China's industry grown? The official statistics show an extremely high average annual rate of growth of 29 per cent over the period 1949-59. While hardly any Western scholar takes this claim seriously, few have inquired into the nature and limitations of the official industrial production index. Fewer still have provided us an independent measure of this rate. Professor Chao's book is a significant contribution to the study of these important problems. Chao's new indexes of industrial production are unquestionably more meaningful than the official one. His excellent critique of the official index is illuminating. In addition, the wealth of data on physical output, prices, employment, wages, and productive capacity presented in this volume should be of great use to other researchers.

The book consists of four main chapters. The first discusses briefly the various formulas of production indexes. The second examines the major deficiencies in the way the Communist Chinese statisticians compute their industrial production index. The third explains in detail the construction of the two new indexes, one including and the other excluding handicraft output. The fourth evaluates the new indexes, comments on the rates of growth, and compares them with an estimate by Liu and Yeh and with those of other countries. The book also contains three appendices dealing with the effects of industrialization and production indexes, the industrial ministries of Communist China, and statistical tables.

The more important results include the following: during 1949-59 industrial output including handicrafts grew at an average annual rate of 21 per cent, as compared to the official claim of 29 per cent; the rate for factory production was 14 per cent, as compared to the official claim of 19 per cent over the period 1952-57; the annual rates of increase were rather uneven with much higher rates during 1949-52 and 1957-59; the subindexes for 13 industries show widely divergent rates of growth and, as may be expected, the producers' goods industries grew much faster than the consumers' goods industries.

On the whole the sources and method of constructing the two new indexes are set forth clearly. The index of factory output, the more important of the two, is essentially based on output series for 74 industrial products grouped into 12 industries. Four of these industries are each represented by a single and more or less complete commodity series. For each of the other eight industries, the output series are expressed as relatives with 1952 as base, and are combined in an arithmetic mean, using as weights factory or wholesale prices of January 1, 1952. The 12 indexes, together with the official index of gross

value of nonferrous metal output, are then aggregated to obtain a general index of industrial production, using as weights the wage bills of productive workers in these 13 industries.

The quality of the new index depends on: (1) the reliability of the 74 output series, (2) completeness of product coverage, (3) representativeness of the product coverage relative to the total product mix, and (4) the appropriateness of the weighting system. Turning first to the weights, one finds that the author is on solid ground. The wage bill weights, as an approximation to value-added weights, are conceptually far more acceptable than the official gross value weights. To compare the official and the new index, one can rewrite the official formula as $\Sigma P_0 Q_0 \cdot Q_1 / Q_0$, and Chao's formula as $\Sigma W_0 \cdot q_1 / q_0$, where $P_0 Q_0$ and W_0 represent, respectively, the gross value and wage bill weights for a given industry expressed as a percentage of total weights, and Q_1 / Q_0 and q_1 / q_0 , respectively, the official and Chao's output index for that industry. Given the two sets of weights and output indexes for 1957 with 1952 as 100,¹ one can compute the following four over-all indexes for 1957 with 1952 as base:

	(Per cent)
(1) Official weights combined with official output indexes	241
(2) Chao weights combined with official output indexes	251
(3) Official weights combined with Chao indexes	191
(4) Chao weights combined with Chao output indexes	196

Interestingly, when different weights are combined with the same output indexes, as in cases (1) and (2), or (3) and (4), the results are fairly close. But when the same weights are combined with different output indexes, the results differ widely as in cases (1) and (3), or (2) and (4). Apparently the difference between the official and the new over-all index is more closely related to differences in the two sets of output indexes for the individual industries than to differences in the two sets of weights.

Chao carefully considers the various possible distortions of the physical output data due to misreporting and mishandling. He goes further and applies "reliability tests" to some output series. First, a consistency check is made by comparing reported output with estimated output derived from technical input-output coefficients or capacity utilization rates and data on input or capacity. These checks show relatively small discrepancies. Second, the technical coefficients and utilization rates are compared with sample means derived from miscellaneous data for individual plants in Communist China and with the coefficients and utilization rates of other countries. When they are found to be not "abnormally high or low," Chao concludes that the consistency checks become reliability checks. It seems to me that these ingenious tests are at best inconclusive. To begin with, numerous questions can be raised about the comparisons in the second step. For example, how meaningful are compar-

¹ The weights and output indexes are given in, or computed from data from: Chao's book, pp. 12, 81, 88, 96, 139, 155; *Ten Great Years*, Foreign Languages Press, Peking 1960, p. 92; J. P. Emerson, *Nonagricultural Employment in Mainland China*, U.S. Government Printing Office, Washington, D.C. 1965, p. 208.

isons between national average coefficients and sample means of different time periods when they may or may not remain relatively constant over time?² How meaningful are the international comparisons when so little is known about the levels of technology in different countries and particularly when there is no logical basis to expect similar rates of utilization of equipment in different countries. But even if one accepts the coefficients as reliable, two other conditions must be met before the consistency checks can become reliability checks: (a) the coefficients must be independent of the output statistics to be checked, and (b) the data on input or capacity, which are applied to the coefficients and utilization rates to derive the estimated output, must also be reliable. Regretfully, these crucial problems have been neglected.

What about the product coverage of the new index? Chao compares the calculated gross value of industrial products included in the new index with the official gross value of industrial production for 1952, and concludes that "the fairly high ratio (74.6 per cent) of calculated gross value to official gross value for all industries indicates that our new indexes have a solid base so far as coverage is concerned" (p. 81). While I have no doubt that the degree of coverage is respectable, I have some reservations about the "fairly high ratio" of 74.6 per cent. This ratio appears to have been overstated for two reasons. First, the denominator of this ratio, the official gross value, is computed by the "factory-reporting method," according to which the gross values of certain products produced and consumed by the same enterprise (e.g., cotton yarn in some textile enterprises) are not counted, and therefore the total is necessarily lower than the sum of the gross values of all individual products. Second, the prices used in computing the official figures are averages for the third quarter of 1952, whereas those used by Chao are prices of January 1, 1952. There are indications that the official prices are generally lower than the Chao prices. According to Chao, the "two sets of prices are drastically different because of the nation-wide 'Five Anti' campaign initiated in mid-January of 1952 and concluded sometime in the third quarter of that year. . . . The first half of 1952 saw a serious drop in commodity prices in most urban centers in China" (p. 32). Another indication is that the prices used in computing the official index are factory prices, whereas Chao uses wholesale prices for consumers' goods and factory prices for producers' goods. The wholesale prices are presumably higher than factory prices since they include distribution costs. In at least one industry even the factory prices of some producers' goods used by Chao are higher than the official ones.³ Because of these complications the official gross

² Six out of 12 comparisons are of this nature (pp. 69-71). One can cite statistics showing rather wide variations in some of these coefficients over time. For example, the utilization coefficient of open hearth furnaces, in tons per sq. meters per day, ranges from 6.67 in 1956 to 8.21 in 1959. *Hsin-hua pan-yueh-k'an* (New China Semimonthly), No. 14, 1957, p. 146, and *New China News Agency*, Peking, Feb. 2, 1960.

³ Taking the output of the five products included in ferrous metal for 1952 (pp. 120-21) and the respective prices (p. 177), one can calculate the gross value of output for Chao's ferrous metal industry at 2,430 million yuan, which is much higher than the official figure of 1,366 million yuan (p. 81). The difference is all the more striking if one notices that the official figure includes, whereas Chao's total excludes, the gross value of iron ore. Be-

value and Chao's calculated gross value are not strictly comparable. Proper adjustments to place them on a comparable basis would lower the ratio of Chao's calculated gross value to official gross value.

Assuming that the author's estimate of the coverage is correct, one finds that for the following four industries the coverage ratio is relatively low: petroleum (14 per cent), paper (22 per cent), metal processing (23 per cent), and daily-use commodities (24 per cent). To what extent does the undercoverage affect the representativeness of the output indexes? Chao classifies the omitted products into military end-products and others. He correctly points out that "as long as the growth rate for the production of military end-products did not exceed the rate of growth for the metal processing industry calculated in this study, the omission of military end-products does not cause any understatement in our overall index" (p. 83). But what is the rate of growth of the metal-processing industry? The author does not provide us a figure. One can, however, reconstruct it from Chao's other figures. If my reconstructed figure is correct, this industry was not growing very fast relative to other producers' goods industries. Its average annual growth rate is 18 per cent over the period 1952-57, lower than all others except those of coal and timber (p. 97). According to the author's figures, the implicit output index for metal processing for 1957 is 232 per cent with 1952 as 100, considerably lower than the 354 per cent for ferrous metal and 370 per cent for nonferrous metal.

As for the omitted products other than military goods, the author assumes that the output of all these products grew at a rate equal to the lowest of the 13 industries (i.e., 6.5 per cent for textiles for 1952-57) and comes up with the conclusion that the omission would cause an overstatement of the over-all rate of growth by 1.4 percentage points. The argument depends critically upon the assumption of a low growth rate. The rationale of this assumption is that the Communists generally release only statistics showing rapid growth. One wonders if this assumption is valid for all the omitted products. Such major omitted items as iron ore, gasoline and other refined petroleum products, non-military metal products, chemicals such as dyes and paints, nonmetallic minerals such as limestone and bricks for the rapid-growing construction industry, and printing and publishing in all likelihood grew faster than textile output which had been seriously restricted by the relatively stagnant agricultural production.

Chao also considers the question of new products which have not been included in the new index. He takes the difference between the official average annual rates of growth and his estimated rates for the metal processing and chemical industry over the period 1952-57, assumes that half of the discrepancy is due to omission of new products and military end-products in these two industries, allows an understatement of the over-all rate of growth by 0.26 percentage point for new products in all other industries, and concludes that the omission of all new goods and military end-products probably could have

cause of this exclusion of iron ore, the author's assertion that coverage for the ferrous metal industry is 100 per cent is misleading.

caused at most an understatement of 1 percentage point in the growth rate of the over-all index. Again the conclusion is rather sensitive to the assumptions involved. How convincing the demonstration is must depend on one's judgment as to the plausibility of the author's assumptions. In any event, there is no error here, the correction of which would yield a higher degree of understatement. The estimated average annual rate of increase for the metal processing used in the calculation (p. 85) is taken from Table 24 (p. 97). It is actually that for machine building and not for metal processing. The latter is lower than the former, and therefore the difference between the official and estimated figure should be larger than that shown on page 85. The adjusted estimate for metal processing alone would result in an understatement of the average rate of the over-all index by about 1 percentage point.

Despite all these reservations the new index of factory production appears to be quite a good one. However, as the author himself points out, the index for the periods before 1952 and since 1957 is of a somewhat different order, because of the lower quality of the statistics for these periods, relatively incomplete coverage, and an unknown margin of error introduced by the assumption that handicraft production in 1958 and 1959 remained the same as in 1957. For similar reasons, the index of handicraft output is not comparable to the index of factory production in quality.

On the whole the study is meticulously documented, and the author handles the intricate Communist statistics admirably. Yet, as is generally unavoidable in any empirical study of the Chinese economy at the present stage, there are some misinterpretations, implicit assumptions, and omissions. Examples: the output of cotton cloth produced in factories for 1949-55 (p. 124) actually includes some handicraft output.⁴ The wage rates used to derive the weights for ferrous metal, metal processing, and textile (p. 155) are those of nonprivate enterprises only.⁵ The prices of coal and petroleum used to calculate the coverage ratios (p. 81) are not given. The price of metal cutting machines (p. 157) is based on a statement that 3.7 tons of ferrous metals were used for every 10,000 yuan's worth of metal cutting machines and tools in 1955.⁶ One also wishes that there had been a list of tables and some annotations in Appendix Table C-1 to indicate which commodities are included in the index.

This book is a pioneering study. It is important to realize that the shortcomings are largely due to the meagerness of information, a matter beyond the power of any researcher. Moreover, these shortcomings by no means detract from the significance of its contributions. The main conclusions still stand. I

have no hesitation in recommending this book to serious students of the Chinese economy.

K. C. YEH

The RAND Corporation

Industrialization and Economic Development in Brazil. By WERNER BAER. Homewood, Illinois: Richard D. Irwin, Inc., 1965. Pp. xii, 309. \$8.50.

Industrialization by import substitution, inflation and economic growth, and the effect of rapid development on the structure of the Brazilian economy are the principal selected topics considered by Werner Baer in this informative and provocative monograph. In keeping with the research objectives of the Economic Growth Center at Yale University which supported this study, the book emphasizes measurable aspects of industrialization and the development and testing of certain hypotheses about the growth process. In addition, the author has made available in an appendix of almost 100 pages, an impressive and valuable array of economic and social statistics for Brazil as well as an incisive commentary on the reliability of Brazilian statistics.

The Brazilian experience offers an unusually interesting opportunity for examining certain aspects of industrialization. From 1947 to 1961, the period studied in depth by Professor Baer, Brazil was in the top ranks of both the developed and underdeveloped countries in terms of over-all economic growth rates (averaging 5.8 per cent per year), in terms of rate of expansion in industrial output (9.6 per cent) and in terms of inflation. Over the period, price levels rose by an average of about 20 per cent annually—as measured by the cost of living index for Rio de Janeiro—with increases as high as 40 per cent in some years. Subsequent to the period studied by Baer, the same index showed even greater increases—52 per cent in 1962, 71 per cent in 1963, and a rate in early 1964 that might have reached 144 per cent on an annual basis if a change in government had not occurred.

The purpose of the study, according to the author, is to examine the process of Brazil's industrialization and some of its effects on different sectors of the economy. As background for his analysis of the 1947-61 period, Baer first presents a brief overview of Brazil's physical setting and historical trends. A second chapter provides a sketchy summary of industrialization attempts prior to World War II. The third chapter tells of the sustained industrialization effort since World War II from the standpoint of policies and the resulting changes in economic structure and over-all rates of growth. The background is completed by a description of Brazilian policy-making institutions.

The most impressive contribution of this study begins in Chapter 5 with an examination of the sources for financing Brazil's industrialization, and the role of inflation. The next chapter examines the linkages through which Brazil's industrialization spread and develops an explanation for Brazil's low incremental capital-output ratio. A final topic is the question of imbalances; in particular, the imbalance between agriculture and industry, and regional disparities. An epilogue comments briefly on the drastic changes in political leader-

ship and economic policy which were initiated in April 1964, after the overthrow of President Goulart.

On the role of inflation, Baer concludes that "it is difficult to notice any drastic misallocation of resources directly attributable to inflation" (p. 132). And he goes further to suggest that "some part of the Brazilian inflation contributed to the real growth of the country through its forced savings aspect" (p. 134) and not necessarily at the cost of lower living standards.

Another interesting aspect of the Brazilian experience emphasized by this study is that Brazil achieved its record of industrialization and growth without comprehensive economic planning and without any real attempt to be selective in the choice of industries to be substituted. And Baer concludes that "it is open to question whether a more selective industrialization policy along the line of the greatest potential comparative advantage could have led the country to growth rates as high as the ones that actually occurred" (p. 193).

The treatment of imbalances and bottlenecks is selective and relatively weak. In the case of agriculture, relatively little field research had been undertaken in Brazil until recently, and as Baer points out in his statistical appendix (p. 210), the agricultural data "are not very reliable." In the absence of good information, Baer's analysis heavily reflects the pessimism concerning agricultural change and the great emphasis on the need for land reform characteristic of much professional and political opinion in Brazil. Since Baer completed his study, there are indications that extensive field research recently undertaken by Professor William Nichols and Dr. Ruy Miller Paiva may present a more optimistic picture of agricultural progress than has generally been accepted in Brazil.

The analysis of regional imbalances by Baer can also be questioned. He seems to accept the traditional view that rapid growth and industrialization accentuate regional inequalities. However, he neglects two important elements. First, he does not recognize that a new trend toward a narrowing of the regional disparities between the Northeast and the South began in 1955, even though this trend is apparent in his Table 7-7 (p. 170). Second, he limits his analysis of regional disparities to the transmission of growth from one region to another through movements of goods, capital, and labor. A crucial factor not considered is the differential effect of external international market forces. Since 1955, the gap between the Northeast and the South has been narrowing because of favorable international markets for the principal export products of the Northeast, namely, sugar, cotton, and sisal. In contrast, the expansion of the South was slowed down by a deterioration in the international market for its principal export product—coffee.

This is a relatively short monograph—aside from the extensive and excellent statistical contributions in the text and appendix—for covering such a large subject as the process of industrialization. Consequently, it should not be unfair to characterize the study as an analysis of selected issues with emphasis on the measurement of *what* has occurred in Brazil rather than on *why* the industrialization effort was so successful. For example, Brazil's industrialization was based almost completely on private enterprise, both domestic and

foreign. What explains the vigorous response by Brazilian entrepreneurs in a situation where the weakness of domestic entrepreneurship has generally been emphasized? Why did foreign private enterprise respond so effectively to the incentives when "everyone knows" that continuing rapid inflation and considerable political instability, which prevailed in Brazil even before the 1961 crisis, are anathema to the foreign investor? Baer has provided an excellent foundation for such further studies of the dynamic forces underlying the industrialization process.

STEFAN H. ROBOCK

Indiana University

Essays on the Chilean Economy. By MARKOS MAMALAKIS AND CLARK W. REYNOLDS. Homewood, Illinois: Richard D. Irwin, 1965. Pp. xxii, 409. \$8.50.

Two of the most important economic problems facing developing Chile are examined in the essays which make up this work. Markos Mamalakis discusses the sectoral impact of the Chilean inflation and the accompanying complex network of government decisions in his "Public Policy and Sectoral Development—A Case Study of Chile 1940-1958." The study by Clark Reynolds, "Development Problems of an Export Economy: The Case of Chile and Copper," part of which appeared about three years ago in this *Review*, focuses on the copper industry, a capital-intensive, foreign-owned enclave which has been the target of divergent analyses.

Both men center their analyses around concepts which, if not completely original, have not been previously applied to Chile. Mamalakis explores the causes and effects of the inflation in terms of "sectoral clashes," defined as "the excessive and administered antagonism and struggle for maximum privileges and advantages between an economy's sectors" (p. 5). These clashes resulted in government policies favoring industry, suppressing agriculture and mining, and remaining neutral toward construction and services.

Reynolds, in asking the basic question about benefits conferred on the Chilean economy by the copper mining companies, turns to a ratio he calls "returned value." Recognizing that the primary sources of benefits stem from expenditures in Chile on wages, locally purchased supplies, and taxes, Reynolds calculates a ratio of these local expenditures to value of production. The higher this ratio of returned value, the greater will be the participation of the export sector within the domestic economy.

Noting the basis for his findings in a 35-page statistical appendix, Reynolds documents the growth of productivity in Chilean copper mining, the more rapid growth of returned value, and the even faster growth of the government's share of returned value. Yet mining failed to serve as a leading sector to propel the rest of the economy out of its widely noted four-decade-old stagnation. Reynolds places much of the blame for this failure on government, which despite its increasing share did not invest copper tax revenues but rather used them for its expenditures on current operations. A valuable source of potential growth was thereby wasted largely on an expansion of the bureaucracy, whose contribution to growth was minimal.

One of the many values of Reynold's essay is the extent to which disaggregation enables the reader to follow the economic forces impinging separately on the three companies mining copper in Chile. Each of them used a different mining process and each, as a result, was faced by different cost conditions. The web of government regulation, too, affected each of the companies in a distinct fashion, and this in turn was reflected in their respective investment decisions. The panorama involving labor costs and labor unions, multiple exchange rates, differential tax treatments, and rates of return on investment are skillfully woven into a framework of analysis which will have value not only for development economists, but also for those concerned with industrial organization and fiscal policy.

The Mamalakis essay, considerably broader in scope, finds the same villain responsible for the Chilean economic stagnation. Chile represents "an instance of unequal sectoral treatment by government in an originally export-oriented economy and a case of intervention which did not succeed in establishing continuous and rapid growth" (p. 171). Favorable government treatment for industrial enterprises, coupled with price ceilings and subsidized competing imports in agriculture, shifted the relative rates of return in these sectors and led to the neglect of agriculture. This view contrasts with that of the structuralist school on inflation, which blames agriculture's torpor on a landed gentry unresponsive to profit incentives. The Mamalakis analysis shows that in those few agricultural sectors where profits were high, production increased dramatically.

Two flaws mar the imaginative set of conjectures expounded by Mamalakis. The first involves a somewhat heroic generalization. The stagnation in agriculture and the growth of consumer-goods manufacturing depended on the relative rates of return in these fields. Convincing empirical evidence about factors influencing these rates is adduced in support of the assertion. On the other hand, in the capital-goods sector, we may simply infer from the absence of production, says Mamalakis, that rates of return were low. Additional evidence on this point would not be at all remiss; as it stands now, the generalization of the rate-of-return hypothesis to cover this sector calls for a considerable amount of faith on the part of the reader.

The other aspect of the essay provoking some concern is Mamalakis' use of statistics. The empirical testing of his provocative hypotheses depends on the reliability of the sectorally disaggregated national income accounts. Despite Howard Ellis' praise in the book's foreword of the "range and quality of [Chile's] statistical information," Mamalakis asks his numbers, derived largely from dated secondary and English-language sources, to do more than they can. He fearlessly uses data from the national accounts which have undergone substantial revision even during the period prior to the book's publication.

These pedestrian details do not detract substantially from the refreshing view Mamalakis has provided on a subject which I, for one, had thought to be exhausted in the literature. Together with the essay by Reynolds, this book will be a standard source not only for Chilean economists, but also for any student of export-oriented and inflation-prone economies.

BRUCE HERRICK

University of California, Los Angeles

Studies in Economic Problems—A Collection of Seminar Papers of the Department of Economics, Calcutta University. Edited by S. K. BASU. New York: Asia Publishing House; Taplinger, distributor, 1965. Pp. v, 256. \$12.00.

This volume consists of 19 essays by 14 authors. Virtually all of the essays deal with some aspect or other of the Indian economy. One wonders why this collection was ever published. Of course, the dust jacket refers to "the penetrating analysis, supported by figures, and the originality displayed by each author. . . ." The reverse would be a generally more apt description. Apart from everything else, no essay was written after 1961. Many of the problems are no longer of substantive interest, and the data are invariably badly outdated.

MORRIS DAVID MORRIS

University of Washington

The Structure of the Slovenian Economy, 1848-1963. By TOUSSAINT HOCEVAR. New York: Studia Slovenica, 1965. Pp. 277. \$7.00; paper, \$5.00.

This book by Toussaint Hocevar is an economic history of Slovenia from the time it was part of the Hapsburg Empire to its present status as a republic in the multination state of Yugoslavia. Spanning more than a century of political and social change, Hocevar's book also provides useful insights into the broader processes of economic development. The author's judgement that self-sustaining growth required an endogenous supply of entrepreneurs, skilled labor, and capital is supported by his observation that, under Hapsburg rule, Slovenian economic process was retarded by a lack of social and economic mobility resulting from ethnic division along class lines. Related to this discussion is Hocevar's hypothesis that economic development presupposes "ethnically conforming institutions," in which the use of a common language is the fundamental criterion of ethnic conformity.

The study is divided chronologically into three parts. The first of these, which describes the era preceding World War I, begins in the preindustrial 1840's with the awakening of nationalism in Germany and the Hapsburg Empire. Developments following Slovenia's industrialization with the help of outside entrepreneurs and capital include agricultural advances, demographic changes, and the rise of Slovenian nationalism, with which the growth of endogenous financial institutions was closely associated. Chapter 5 concludes Part I with a consideration of "Ethnicity and Economic Development," the central theme of the study.

Part II is concerned with the interwar period, the inclusion of Slovenia in the multination-state Yugoslavia, the growth of industry, agriculture, and business, and the evolution of new socioeconomic and political institutions on an ethnic basis. In Part III, which deals with Socialist Yugoslavia in the post-war era, the author examines the consequences of socialism for agriculture and industry, and discusses the role of Slovenia within a multination state.

A wealth of historic information concerning Slovenia's industrial growth is presented, starting with the establishment of social overhead capital in the form of railroads, coal and steel industries, and hydroelectric power. Subse-

quent developments include a gradual shift in emphasis from basic industries to the manufacture of more sophisticated products and a rise in the significance of service industries.

The role of agriculture in Slovenia's economic development is also appropriately emphasized. With the abolition of the feudal system in land tenure in 1848, peasants began to respond to the incentives of an increasingly monetary economy which encourages modernization and intensification of farming methods. New markets for farm products followed urbanization, improved transportation, and the liberalization of trade, while an expanding industrial complex absorbed some of the oversupply of farm labor.

Economic development in Slovenia, as elsewhere, was accompanied by a disruption of traditional patterns of living, particularly among the peasants. Similar to the experience of the United States and Western Europe, rural-urban migration in Slovenia tended to swell during prosperity and to subside during periods of depression. Economic progress was frequently interrupted when business depressions which originated in more highly developed countries were transmitted to less developed economies via foreign trade. Agriculture in Slovenia also suffered when farm prices fell during the latter part of the nineteenth century under the impact of growing wheat supplies from North America and Russia.

In the decade 1891-1900, emigration from Slovenia rose to over two-thirds of the natural increase in population. Hocevar's view that this represented a regrettable loss of manpower and investment in human resources does not take account of the possibility that, without a sufficiently broad industrial base, emigration may actually contribute to economic development by reducing population pressures on limited natural resources.

Following World War II, when Slovenia had been a part of Yugoslavia for a quarter of a century, a complete revamping of social, economic, and political institutions took place under socialism. The new regime, after making an unsuccessful attempt to concentrate decision-making authority in Belgrade, was unable or unwilling to impose the police-state methods of the Stalin era on its people, and reluctantly resolved to decentralize. The complete reversal of farm-collectivization policies which followed may be viewed as a victory for peasant individualism and a defeat for the Communist rulers.

Despite these setbacks for the regime, economic progress under socialism has been significant. Production has increased through ruthless exploitation of natural resources, continuous operation of the industrial plant, and foreign loans. Slovenia, the most developed area of Yugoslavia, has been called upon to contribute a vastly disproportionate share to the national economy via large-scale transfers of capital to other Yugoslavian regions.

Hocevar contends that such redistribution of income among nations in a multination state should be severely restricted if not eliminated, both on ethical grounds and "because large-scale transfer of income from Slovenia reduces her potential product by more than it increases the product in the region which is the beneficiary of income transfer." He suggests that, instead of retarding the development of Slovenia in this fashion, the central government should seek massive foreign aid to raise and maintain consumption and social

standards in less developed areas at levels comparable to those in the more developed regions. It seems questionable, however, that his recommendation would be accepted either by the Belgrade government or by potential donors of foreign aid, for the redistribution of income within a sovereign nation is accepted practice in many countries and is subject, as often as not, to political rather than to cost-benefit considerations.

Hocevar's book makes a valuable contribution by bringing together an abundance of source material on the economic history of Slovenia which is otherwise not readily accessible. His thesis, which points to ethnicity or nationalism as a potentially constructive force in economic development, merits thoughtful examination. His position would have been strengthened by a consideration of the works of Rostow, Myrdal, and others who emphasize the role of emerging nationalism in economic development. Although Hocevar does not generalize from his findings, his discussion may have useful implications for studying the problems of economic, social, and political integration in other ethnically diverse countries such as Belgium and Canada, and in potential supranational entities such as the European Common Market. Hocevar's study is a sharply focused, scholarly work on the economic history of Slovenia and an investigation of some of the key factors in Slovenian economic development.

H. W. BAUMGARTNER

State University College, Oneonta, New York

Das Wachstum der deutschen Wirtschaft seit der Mitte des 19. Jahrhunderts.

By WALTHER G. HOFFMANN WITH FRANZ GRUMBACH AND HELMUT HESSE. Berlin, Heidelberg, New York: Springer Verlag, 1965. Pp. xxvi, 842. DM 138.00.

In August, 1965, Professor Hoffmann published a detailed account of the growth of the German economy since the middle of the nineteenth century. This monumental work is the most comprehensive empirical study to date of long-run German economic growth. The preparation of this study took several years and occupied more than a dozen co-workers. The effort was worthwhile. Hoffmann's work, which is 842 pages long and contains 26 graphs and 325 tables, fills gaps in our information which have until now dismayed many a student interested in the long-run development of the German economy. The bulk of existing statistical information on the growth process has now been collected in one volume.

Some of the data presented in the book, most of which are time series, go as far back as 1817. For the years before 1871 statistical information available on the area of the Reich as a whole is poor. To establish time series for the earlier period required a very close study of the statistics published by the statistical offices of the various independent German states which existed before 1871. Needless to say, until now these scattered data were either not accessible to most research workers, or they were useless without an intimate knowledge of the contemporary political and institutional structure.

Primary statistics which were collected in the nineteenth century, and for that matter during much of the first part of this century, give useful informa-

tion for a variety of purposes, yet they are generally of little use for modern growth analysis. The necessary raw material for the latter are time series on aggregate output, employed labor, and productive capital. These series are now available. They were established for the economy of the Reich as well as for different sectors. For the period after World War II, the series refers to the area of West Germany. East Germany is unfortunately not included in the study.

The extension of the study into the 1950's provided a convenient check on the methodology employed in transforming 19th century primary data into time series useful for growth analysis. The derived time series for post-1948 can be compared with official time series. It was found that the two sets of data are both consistent and similar, which is reassuring. However, the authors advise the use of official West German data and not the series given in this volume for postwar studies.

The book falls into two parts. The first, consisting of 165 pages, summarizes the main results of the study. Among the topics discussed are the origin of national product, population growth, employment, and labor productivity. Other topics are the growth of the capital stock, technological progress, production in different sectors of the economy, income distribution, and the use of the national product. The first part ends with an investigation of the development of foreign trade. A final section is devoted to a comparison of different long-run national income estimates for the German economy.

The second part of the book provides a finer breakdown of the aggregates analyzed in Part I. The data on the capital stock are very detailed. There are remarkably good data on changes in the structure of consumption, the agricultural sector, as well as on some industrial sectors. Students of public finance can find time series on the long-run growth of public expenditures, while those interested in investment financing are provided with detailed data on the assets and liabilities of different types of financial institutions. There is a long-run series on currency in circulation. A long-run series for the total money supply, for which many readers may look, could, however, not be established.

What are the most important findings of this study? The primary intent of the authors was to compile data on the progress of long-run economic growth. In this they fully succeeded. There is indeed a mountain of data waiting for further evaluation. From what the authors themselves have analyzed, the following over-all picture emerges.

In 1913 constant prices the net social product increased annually by 2.6 per cent between 1850 and 1913, and 2.8 per cent between 1872 and 1913. (This compares with an annual increase of 6.6 per cent for West Germany between 1950 and 1959.) Population increased after 1820 from .8 per cent to 1.4 per cent. If we assume that the average population increase was around 1 per cent, the long-run increase in real per capita social product was 1.8 per cent before 1913. It is not possible to give a detailed account of the many underlying structural, institutional, social, and technological changes influencing this expansion within the compass of a review. The interested reader will find abundant material on this in various chapters.

The growth rates cited above reflect rapid capital formation (the capital

stock in 1913 constant prices increased 3.1 per cent annually between 1852 and 1913, and 8.3 per cent between 1950 and 1959) and a considerable ability to innovate and apply new technologies. One may also observe another important feature of the growth process. According to this study, labor productivity per hour worked rose 1.8 per cent per annum over the period 1850-1913. Yet from Gerhard Bry's 1960 National Bureau study of wages in Germany, one can estimate that real wages in industry (certainly the highest-paid sector) rose on the average, at most, 1 per cent per annum during the period 1871 and 1913. The rate was presumably less for the whole period 1850-1913. The German takeoff into economic growth was thus accompanied by a serious lag in real wages, something which was witnessed again in the *first* phase of West German economic growth after 1948. This study finds (p. 87) that, using a wider definition of labor income than official West German statistics, the labor share in income fell in both periods. This will explain part of the high rate of capital formation and the ability to implement new technologies quickly. There remain however a number of puzzles to be solved.

Never before in German history has economic growth been so rapid as that in West Germany after the last war—and, we may add, also in East Germany, though there under a different order. There must have been some kind of breakthrough to overcome a low level 2.6 per cent (and in the interwar period even lower) real growth rate. A number of explanations have been offered for this. Some authors have given as a reason for West Germany's economic revival and growth the return to a free-market system, others the full integration into the world market, and again others—among them this reviewer in a recent book—public policy with respect to the volume and structure of capital formation. The reader of this study is left to wonder what Hoffmann might have to say—perhaps in another book—on this challenging subject.

In view of the importance of this book the reviewer hopes that it might be possible for the authors to produce a special, separate summary of the sources used in this study and, in particular, a description of the methods of derivation of the time series. This would greatly enhance further research. Further, for the benefit of English-speaking economists, an English edition would be very desirable.

All in all, this book is a major contribution to the understanding of the long-run economic growth of an important industrial country. For this work the economic profession will be thankful to Professor Hoffmann.

Statistical Methods; Econometrics; Social Accounting

Toward Income Equality in Norway. By LEE SOLTOW. Madison and Milwaukee: The University of Wisconsin Press, 1965. Pp. xviii, 155. \$10.00.

This book is a bold and imaginative exploration of a fantastically rich body of data for the study of the size distribution of income.

The basic source materials consist of annual assessment books of eight Norwegian towns ranging in population in 1960 from 2,000 to 28,000. The books

contained each resident's name, address, vocation, income, and wealth. Four of the towns were in a county marked by rapid population growth and industrialization during the past century (Östfold) and the other four from a county with slower growth and less industrialization (Vest-Agder). Stratified samples of at least 40 male names including all of the upper tenth of income earners were generally taken for each town in each of the 15 years selected for study by the author within the period 1840 to 1960 (although there were missing cells because many books for the 19th century dates were lost). There were, of course, a number of data problems such as changes in the definition of income and under- and overreporting of incomes which appear to have been handled in a careful, thorough, and judicious manner. The Gini concentration ratio (equivalent to the arithmetic mean difference between incomes for all pairs of individuals) is the measure of inequality mainly employed in the study.

Professor Soltow uses these materials and this measure to study the long-run trend in the distribution of income in the eight cities (both in over-all terms and for specific income groups), the relationship between wealth and income changes, lifetime income distributions, the relation of sociopolitical changes to the income distribution, and the redistributive effects of public finance.

The evidence points to a sharp decline in inequality. Much of the decline had occurred by the turn of the century; city concentration ratios of around 0.60 and 0.70 in 1840, 1845, and 1855 had been replaced by ratios of around 0.40, and in Sarpsborg, the Östfold city with the greatest population growth and industrialization, the ratio was less than 0.30. The Great Depression caused inequality to rise but the downward trend was resumed after the war and by 1960 the concentration ratio was around 0.30 for seven of the cities, and a little over 0.40 in the eighth.

An important issue about which little is said concerns the extent to which these findings relating to eight towns may be applied to all of Norway. At one point at least (p. 61) the author suggests that the findings may be generalized in this way, and this does not on the whole seem implausible to the reviewer. However, there are important sectors omitted from the study. About 6/7 of the Norwegian population was rural in 1865 and 2/3 was rural in 1960¹ (although only 1/4 of the rural labor force was engaged in agriculture). Also, Oslo, to which the author makes no reference, included about 1/6 of Norway's urban population at the beginning of the period and 2/5 at the end.

The author delves into the history of the country and the individual towns to try to find the reasons for the decrease in inequality. He concludes that the important factors included (1) the breakdown of monopoly positions (particularly with the end of mercantilist restrictions); (2) the weakening of the influence of property incomes as property ownership became more dispersed, more public, and less lucrative, at least with respect to rents and interest pay-

¹ A question about the behavior of the concentration ratio in the rural population is raised by the lack of any decline in inequality between 1900 and 1950 (the terminal years for which data are available) in the town of Farsund, which in size, growth, and occupational distribution may be closer to the rural areas than the other cities.

ments; (3) a diminution in seasonal unemployment due to a decline in the relative importance of the timber and shipping industries with the rise of factory employment; (4) public policies such as transfer payments, progressive taxes, and full employment; (5) increasing equality in educational opportunity; and (6) reduced differentials for ability.

The data enabled the author to explore a variety of other interesting matters. In a study of specific income groups, based on Sarpsborg data, he shows that income dispersion declines sharply when the two bottom tenths and the top tenth of the distribution are eliminated, but remains relatively constant when further layers of the distribution are peeled away. Over time, the mean incomes of the top tenth dropped from 5 times the over-all mean income in 1855 to 2.5 times in 1960. The author finds, however, that even for the middle classes (from the 20th to the 80th percentile) the redistribution effect was not as important as the growth effect; their percentage gain in relative income was only about half of the over-all rate of growth in real per capita income. The inequality within the top tenth has not tended to diminish and, relative to inequality within other tenths, it has increased.

One chapter is devoted to a study of the relation between wealth and income for 439 men in one city who were between 55 and 64 years of age in 1960 and for whom income data for 1930, 1938, 1950, and income and wealth data for 1960 were available.² When 1960 wealth is regressed against the incomes for each of the four years, the coefficient for 1960 is, as would be expected, larger than that for the earlier years, but not overwhelmingly so. The author estimates that the elimination of the above-average wealth of the top tenth of the income distribution (which had 45 per cent of total wealth and 24 per cent of total income) would reduce the 1960 concentration ratio for the group under study from 0.243 to 0.188.

Through the device of transition matrices using a 2×2 cross-classification table, the author estimates that only small increases in inequality would occur if the relationship between father's 1930 income and son's 1960 income persisted through time for many generations. On the other hand, the persistence of changes for a given group of men as they grew older would in itself tend to produce marked increases in inequality.

For his study of lifetime income changes the author was able to analyze income data for every other year from 1928 to 1938 and from 1948 to 1960 for 121 men who were 55, 60, and 64 years old in 1960. He finds that the concentration ratio declines from the average annual ratio by 4.4 per cent when the accounting period is extended from the first year alone to the first two years, by 10.3 per cent when the first three years are included, and by 26.9 per cent when all the years are combined. These changes are somewhat larger than the reviewer found in an earlier examination of longer-than-one-year distributions for Delaware, Wisconsin, the United States, and the United Kingdom,³ but differences in places and methods could easily account for this.

The author is continually conscious of the relevance of the income distribu-

² Actually, wealth data were available for only 325 of the men.

³ *Structure of Income*, pp. 268-79.

tion to the functioning of the economy and the society at large. He concerns himself at a number of points with the impact of the changes in inequality on saving and investment and thus on economic growth. Among his more important findings here is that the increase in equality did not come at the expense of high investment. The fraction of gross product invested in Norway has been very high relative to the investment ratio of other countries owing to a policy of high taxation and high public investment. The increase in public capital has been almost as large as the rise in private capital. The Norwegian tax system is in general much more progressive than that of the United States.

Not all of the author's efforts at explanation seem felicitous to this reviewer. For one thing, Soltow attempts to explain the impact of the economic changes outlined above in terms of Rostow's stages of growth, using Rostow's dates for Sweden. Both the movement of the concentration ratio over time and the timing of the economic changes make this a rather unconvincing exercise. Several different sets of "distinct periods" could be justified as easily as those selected by the author from the chart showing the movement of the concentration ratios over time, and a number of changes assigned to one period or another (e.g., welfare legislation) really occurred over two or more "periods."

Secondly, he regresses the concentration ratio against city size and finds less inequality in larger cities and greater decreases in inequality in faster-growing cities. His explanation is that high incomes tend to be diluted by an increase in the number of incomes. This is a far from adequate explanation and is not necessarily correct even on a mechanical level. The concentration ratio is likely to decline when new incomes are added that are within the existing range of incomes and to rise when the new incomes are above or below the existing range. Immigrants might conceivably be accepting incomes lower than those commonly paid to natives, and if this were the only factor at work, inequality might rise.⁴

Third, the author regresses the concentration ratio against an "occupation index" derived by assigning arbitrary values to different occupations, such as one to artisans and five to factory workers. The regression coefficient is highly significant (though here as in most of his other regressions the author fails to give us the correlation coefficients), but it is difficult to assign any meaning to the index. One wonders why he did not regress the concentration ratio against some more general and less arbitrary indicator of economic development, such as some measure of real income.

Finally the author is inclined to regard his measure of income dispersion as a measure of the amount of incentive in the economy; the diminution in inequality, it is implied, has reduced incentives, *pari passu*. Of course, some dispersion of income is necessary to maintain incentives but there is no reason to suppose that changes in the size of pecuniary incentives can be gauged di-

⁴Incidentally, the rise in the concentration ratio for Vest-Agder County from 0.567 in 1840 to 0.732 in 1845 raises a question about the author's rejection (pp. 45-46) of Kuznets' speculation about an early stage of increasing inequality. Also the effect of the shift from the rural to the urban sector, which is not reflected in Soltow's inequality measures, was an important factor in leading Kuznets to suggest that inequality might increase before it declined.

rectly from the changes in dispersion. This is not, of course, to dispute the author's finding that the growth in equality in Norway has been associated with sharply reduced age and skill differentials.

However, the positive virtues of Soltow's volume far outweigh these criticisms. His book provides valuable insights into the associations between income distribution and economic growth. Our knowledge of these relations can grow only through further work like this, which will include the rural sector of Norway, and Oslo, and beyond this other countries. Meanwhile we have here an important contribution to the study of income distribution.

Supply and Costs in the U.S. Petroleum Industry—Two Econometric Studies.

By FRANKLIN M. FISHER. Baltimore: Johns Hopkins Press for Resources for the Future, Inc., 1964. Pp. xiii, 177. \$5.00.

In this volume, Professor Fisher reports results from two imaginative empirical studies which he made of costs in the U.S. petroleum industry. The first concerns the relation between petroleum well-head prices and the number of new wildcat wells, the success ratio in wildcat drilling, and the average size of new discoveries. The second considers the relationship between drilling cost and well depth. Both studies are excellent examples of insightful, balanced, econometric analysis in which very crude data end up supporting a plausible set of hypotheses about the petroleum industry.

The principal conclusion in the first study is that although the price elasticity of wildcat drilling is quite high, 2.85, the price elasticity of the total volume of new discoveries is only about 0.31. The average size of a new discovery in a successful wildcat declines when prices rise, and the success ratio, the ratio of productive wells to total wells drilled, may also fall. While the theoretical explanation for these results is very similar to Ricardo's extensive margin, Fisher's empirical estimates are interesting.

Are the estimates reliable? Fisher's data consist of annual observations on each of the five national petroleum districts during the period 1946-55. Each of the three dependent variables is related to a deflated well-head price, geophysical and core-drilling time, average discoveries of natural gas, lagged values of the success ratio, the size of new oil discoveries, and drilling depth and dummy variables. Sampling across districts as well as over time is a convenient device for increasing the number of observations; well-head prices apparently vary considerably across districts on a given date. A minor shortcoming of this study is that Fisher neglected to display the small volume of data which he examines.

His analysis requires an assumption that intertemporal and interdistrict price variations are similar in their effect upon wildcat drilling and new discoveries. Fisher states that he is primarily interested in "long run" responses, although he declines to explain what long run means or why they should be interesting. From a policy point of view I would prefer to know how price changes will affect wildcat drilling during the next year or two, not in the dis-

tant future. Whether or not short-term predictions are necessary for policy, he concludes that sampling across districts on a given date tends to overstate estimates of long-run price effects.

In addition he uses lagged values of the success ratio, size of new discoveries, and drilling depth to take into account "district effects." (For some reason lagged new wildcats were ignored.) Lagged variables were also intended to measure "the underlying process which determines prospect characteristics and as indications of what wildcatters can expect, they have economic influences" (p. 21). The use of lagged endogenous variables will yield biased estimates of parameters if residuals are not serially independent. There can be little doubt that his residuals pertaining to a district will exhibit positive autocorrelation.

He also reports an attempt to allow for district effects with dummy variables, but does not publish the estimated equations on the grounds that they "make results strictly applicable only to the short run . . ." [and] ". . . the equations already presented may be taken to contain the most valid results" (p. 32). When dummy variables are included, the price elasticity of new wildcats falls to 1.5, which remains significant although all standard errors rise. Readers should be given the opportunity to decide which equations contain the most valid results.

The second study, concerning the relationship between drilling costs and depth, attempts to (1) estimate an obviously critical cost relationship in the petroleum industry, (2) determine how technological change affected this relationship over a four-year period, and (3) apply nonlinear estimation techniques. The basic structural equation is:

$$Y = K(e^{aX} - 1),$$

where X is the depth of the well in feet and Y measures cost per well in dollars (excluding overhead). Fisher's estimates suggest that (1) for a large number of drilling areas, costs at least double every 3500 feet, (2) technological improvements have more than offset any tendency towards diminishing returns in drilling and were particularly favorable to shallow wells, and (3) his nonlinear function fits the data well.

His data are from the 1955, 1956, and 1959 Joint Association Surveys of Drilling Costs. The function was fitted for each of a number of drilling areas. Apparently to prevent disclosure, these surveys could only be used in a very condensed form; a maximum of nine points was available for fitting any curve. Nevertheless, the approach and results are suggestive and should stimulate more work in this area.

In conclusion, it is easy to agree with the author that econometric analysis of trade association data should help when evaluating policy questions. However, crude data can at best provide weak evidence for such questions. Students of the petroleum industry can seriously challenge and refine Fisher's conclusions only by applying a similarly imaginative approach to better data.

DONALD HESTER

Yale University

Le coût de la vie à Paris de 1840 à 1954. By JEANNE SINGER-KÉREL. Paris: Librairie Armand Colin, 1961. Pp. 560.

The title *The Cost of Living in Paris from 1840 to 1954* seems to suggest an important but dull book, boringly loaded with statistics. Perhaps the following thoughts offer some comfort in approaching this 560-page book. To the extent that the cost of living in Paris is (or was) representative of the French cost of living, such a study would be of crucial importance to those wishing to study the process of French growth. The cost-of-living index of major cities is used as a price deflator for many a developing country. Numerous economists may find such indices useful. Some may be interested in French growth per se, others in testing the hypothesis "history repeats itself" in the context of a comparison between past French growth and present developing countries' economic change.

The book is well organized, a marked quality in such an endeavor. This attribute will make the book easily usable by the non-French-speaking researcher, and its main use will be as a statistical handbook. The first six chapters report the existing indices for various subperiods within the whole period and compare them with foreign indices. Then the methodology is discussed. In the two following chapters the indices are given, and their movements are compared with indices estimated from other sources. Then follows a study of individual items composing the whole. A chapter on the relative variations of prices within the whole ends Part I. The rest of the study incorporates four annexes. Annexes I to III cover notes, and Annex IV gives the data for the indices themselves. The care, precision, and conciseness with which the study is handled are highly commendable.

Familiarity with Chinese ghost stories might help sustain one's patience while exploring the maze of difficulties raised by index numbers. The Bureau of Labor Statistics' definition of the cost-of-living index is "... (in such an index) we would try to measure the changes in the cost of an equivalent market basket of goods and services whereas in a price index we try to measure the same market basket."¹ Presumably the first problem to face in such an endeavor is the form to choose for the index. The author chooses to make a set of Laspeyres indices with and without chaining. The Laspeyres index uses base-year weights. By making a series of binary comparisons between adjacent periods, the impact of the items excluded would be reduced. The Paasche index uses current-year weights. Either index introduces a bias, and it is believed that the "true" index would be the geometric average of the Laspeyres and the Paasche indices, i.e., Fisher's ideal index.² In fact the appropriate "true" index might be a constant-utility or welfare index. Whether or not such an index is meaningful or achievable is another question, which would be answered by P. A. Samuelson by an emphatically unambiguous no.³ The problem of welfare is pervasive, even for the Bureau of Labor Statistics, as is ex-

¹ Sidney A. Jaffe, "The Consumer Price Index—Technical Questions and Practical Answers," *Am. Stat. Assoc., Proceedings*, 1959.

² See Y. Barzel, "Some Observations on the Index Number Problem," *Econometrica*, July 1963, 31, 391-99.

³ P. A. Samuelson, "Evaluation of Real National Income," *Oxford Econ. Papers*, New Ser. II, Jan. 1950, 1-29.

emplified in the following quotation: "There is one very important recommendation with which the Bureau of Labor Statistics cannot agree, even with modifications. This is the recommendation that the Consumer Price Index be reoriented gradually toward a 'welfare' or 'constant-utility' index. We would see some value in having a 'true cost-of-living' or constant utility index if techniques can be developed for defining such an index unambiguously, and then for compiling it objectively."⁴

The difficulties of welfare evaluation have been reduced in the book by the use of classes of spenders, i.e., workers (wage earners) versus the bourgeoisie. In this manner two sets of indices have been obtained. Each index comprises 213 items. Once the actual indices are obtained, their behavior over time is analyzed and explored. International comparisons with foreign indices (U.S., U.K., Sweden, Denmark, Belgium) are made in order to isolate the international influences from the domestic ones. Since M. Gilbert and I. B. Kravis' study for the OEEC in 1950,⁵ it has become customary to consider the purchasing power parity problem in international comparisons. There is no trace of this in the book. The trend movements in the indices covering 213 items are compared with those of partial indices from other sources.

In order to isolate the important domestic influences on the cost of living, various coefficients (dependence, correlation, etc.) have been calculated between the cost of living and wholesale prices and wages, respectively. Presumably the idea is to isolate cost-push influences (wages) from demand-pull pressures (wholesale prices). Generally the results show that these influences vary from subperiod to subperiod. Besides the statistical computations of coefficients, there does not seem to be a satisfactory economic analysis of these aspects. There is also the problem of price variations owing to technological change. This aspect is not mentioned in the book.

Potential uses of the indices as suggested by the author in the introduction are distribution (debtor vs. creditor), capital formation (wages vs. other revenues), public debt and monetary policy, time perspective of contractual behavior, attitude towards risk, spending vs. savings. Judgment must be exercised in solving individual problems. For instance the cost-of-living index can hardly be used as a deflator for real income comparisons (see Samuelson). On the other hand, since the author has painstakingly collected an admirable amount of expenditure data, one wonders whether related research could not be pursued—for instance, the testing of revealed preference axioms (i.e., the "rationality" of consumers) à la Koo-Dobell,⁶ as well as the investigation of the shapes of Engel curves.⁷

Economic Systems; Planning and Reform; Cooperation

The Best Use of Economic Resources. By L. V. KANTOROVICH. Cambridge, Mass.: Harvard University Press, 1965. Pp. xxxiii, 349. \$15.00.

The English translation of *The Best Use of Economic Resources* was eagerly awaited by bourgeois economists for a number of reasons. Economists with a special interest in programming and production theory wanted to honor the discoverer of linear programming by reading his own presentation of his discovery and to gain the insight that only the words of an original thinker can convey. Students of trends in Soviet economic thinking wanted to study at first-hand the position of Academician Kantorovich, winner of the Lenin Medal for meritorious scientific achievement and most eminent exponent of formal, mathematical methods of planning. The second group of students will find in, and particularly between, the lines of this book many valuable clues to the state of current economic thinking in the Soviet Union; the first group, those interested primarily in the economic significance of linear programming, will be seriously disappointed.

The book is neither text nor treatise, but a tract addressed to Soviet economists and planners, exhorting them to more rational methods of economic calculation. What are these more rational methods? That is the key question, where both Kantorovich and his reviewer must proceed delicately.

For it must be recognized that Soviet methods of economic calculation are already based on a scientific and objective foundation, the Ricardo-Marx labor theory of value. This cannot on any account be denied or contradicted. Yet the labor theory of value, like any other doctrine, can be applied correctly or incorrectly, and it is Kantorovich's contention that it is being applied incorrectly in much contemporary analysis, leading, thereby, to substantial economic waste.

To summarize the situation: The labor theory of value holds that the value of anything is the amount of socially necessary labor time needed to produce it. If this statement be taken as a definition of value, it is innocuous but not very helpful. The doctrine, therefore, holds more: that goods and services tend to exchange at prices that are proportional to their values as so defined. These assertions are as true of labor-time as of any other commodity and, since less than a man-year of labor is required to support a workingman and his family for a year, a residue called surplus value arises whenever a laborer is employed. Under bourgeois capitalism this surplus value becomes the property of the employer. So it is that the theft of surplus value, i.e., the exploitation of workingmen, is inherent in the capitalist system of organization. I recall this familiar argument because it in effect defines the word "value." That word must be interpreted in a way that does not undermine the intellectual edifice that has been erected upon it.

One important amendment has to be made to my sketch of the labor theory of value. When I called it the Ricardo-Marx labor theory of value I meant early-Ricardo and early-Marx. Late-Ricardo does not concern us. But late-Marx, the Marx of Volume III, perceived that things were not quite so simple.

The organic composition of capital, that is the proportion of constant capital (plant, machinery, etc.) to variable capital (labor costs), is different in the production of different commodities. Only variable capital gives rise to the surplus value that can be appropriated by the capitalist exploiters. It would follow, therefore, if prices were proportional to values, that rates of profit would be different in different industries, which clearly is not so. So the notion that commodities tend to exchange in proportion to their values has to be relinquished. It is still true of labor, but when it comes to the commodities produced by labor under the aegis of capitalist employers the law of supply and demand takes over and prices adjust so that the rate of profit is the same in all industries. This amendment, however, does not affect the essence of the demonstration that exploitation of the workers is inherent in capitalism. For the effect of these price adjustments is merely to shift the attribution of surplus value from industries with higher than average organic composition to those with lower than average organic composition. On the average it is still true that commodities sell in proportion to their values. Just which capitalist appropriates the surplus value is not important; what is of the essence is the relationship between the classes and the fact that the capitalists, as a class, exploit the laborers as a class. Thus the late Marx did not hold quite so simple a version of the labor theory of value as the early Marx, but the essence of the early argument persisted. We shall see that Kantorovich has elaborated the labor theory of value even farther, perhaps dangerously far. But to do this we have to recapitulate two other threads of doctrine.

First it has to be remarked that vulgar, bourgeois economists do not reason in the way outlined above. They cannot, of course, ignore the fact that the goods produced by a worker sell for more than the wages he receives for producing them, but they interpret it differently. They attribute the surplus to the contributions of other factors of production, such as land, plant and equipment, and so on. By this intellectual device (the so-called marginalist or neoclassical theory of value), they purport to impute the entire price of a commodity to one or another of the factors of production that cooperate in producing it, so that the rate of profit (the excess of price over the costs of the factors of production, expressed as a percentage) tends to be zero. It is precisely against this attribution of value to factors other than labor that the staunch Marxist economist must stand firm.

The remaining doctrinal thread comes from linear programming itself, a mode of economic analysis which Kantorovich discovered in 1938-39 and George Dantzig rediscovered, in a capitalistic environment, in 1947. The odd thing is that Kantorovich's discovery had virtually no impact on economic thinking, in the USSR, or elsewhere, while Dantzig's rediscovery set off an enormous vogue. There are several reasons for this. Linear programming has both practical and theoretical implications. On the practical side, Kantorovich's discovery was a bit early and perhaps in the wrong environment, while Dantzig's rediscovery occurred in exactly the opportune time and place. As to timing, the implementation of linear programming requires extremely onerous arithmetical calculations, computations that can hardly be envisaged without the assistance of an electronic computer. The year 1939 was too early, but by

1947 adequate computers, though not yet on hand, were clearly in prospect. The first illustrative application of linear programming in this country was done laboriously by hand; the second was mechanized. As to appropriateness of place, the conclusion is a bit more conjectural. The method cannot be applied, even now, to the planning of so vast a system as an entire economy. It can handle a plant or, at most, a firm with a few plants. Hence it is adapted to a system of economic organization in which plant managers have the incentive, the resources, the authority, and the responsibility for devising and improving their operating plans. This seems to be more nearly true of a decentralized capitalist system than of a thoroughly rationalized socialist one. At any rate, capitalist managers quickly began experimenting with linear programming; socialist managers did not.

On the theoretical side there is a fundamental difference between the contexts in which the two discoveries occurred.

The principal significance of linear programming for economic theory is contained in the duality principle, which was discovered by A. W. Tucker, D. Gale, and H. W. Kuhn shortly after Dantzig announced his finding but was known to Kantorovich long before that. According to this principle, the direct solution of a linear programming problem yields an economic or business plan that employs the available resources as efficiently as possible and, at the same time, determines certain auxiliary variables (variously called dual variables, shadow prices, and by Kantorovich, objectively determined valuations) of great economic significance. One of these objectively determined valuations, to use Kantorovich's term, corresponds to each of the economic resources involved in the problem, and its value tells how much the economic value of the output could be increased if one additional unit of that resource were available. In slightly different words, the objectively determined valuations tell how much the economic unit for which the plan is constructed should be willing to pay for one additional unit of each resource and thus, in this bourgeois sense, correspond to the values of the resources. Furthermore, if the objectively determined valuations be interpreted as resource values per unit, the total value of the resources available to an economic entity is precisely equal to the value of its output.

Thus it appears that these objectively determined valuations have many of the properties of the marginal value products employed in bourgeois economic thinking. Indeed, it was early recognized that the objectively determined valuations are nothing but marginal value products,¹ and it was this insight that led to the great burst of interest in linear programming on the part of capitalist apologist economists. For it meant that the whole elegant mathematical apparatus of linear programming could be brought to bear on the problems of value (in the bourgeois sense) and general equilibrium. Linear programming became a powerful analytic tool for perfecting the Walrasian theory of general equilibrium in the hands of L. W. McKenzie, H. W. Kuhn, and a number of others, culminating in G. Debreu's *Theory of Value*.

By the same token that objectively determined valuations correspond to

¹ For a lucid, but not particularly early, exposition of the relationship, see T. C. Koopmans, *Three Essays on the State of Economic Science*.

value in the bourgeois sense they appear, at least superficially, inconsistent with the concept of value disclosed by scientific Marxist analysis. This explains why linear programming was greeted with far more enthusiasm by bourgeois economic theorists than by Marxist theoreticians. One of Kantorovich's main tasks is to show that this appearance of a conflict between objectively determined valuations and the labor theory of value is only superficial. If the labor theory of value is properly construed, he maintains, it will be seen that the computation of objectively determined valuations is the scientifically correct way to calculate values in the true Marxist sense. For example:

The problem naturally arises as to whether they [objectively determined valuations] are in contradiction with the labour theory of value, according to which, under socialism as well, the value of products must be determined by the socially necessary expenditure of labour.

Analysis of this problem shows that the structure of o. d. valuations associated with an optimal plan is in complete agreement with the labour theory of value; furthermore, the methods for finding these valuations provide an approach to calculating the full social expenditure of labour (p. 290).

This is one of the two main theses of the book; it is reiterated on pages 47, 62, 75, 105, 107, 121, and a number of other places that I neglected to note. The other main thesis is "... that a system of production valuations correctly constructed and conforming to real conditions is an effective means of analyzing the best use of available resources. . . . Such a method is superior to existing ones because many factors usually disregarded or only considered qualitatively are accounted for by quantity; as a result the choice of the solution conforms more fully to the national economic interest" (p. xvii). This conclusion is unarguable, and I shall not discuss it.

How, then, can the objectively determined valuations, which as a matter of implacable mathematics correspond to bourgeois marginal productivities, be said to be consistent with the labor theory of value? In the first place, Marx was perfectly explicit that "socially necessary labor time" includes both direct and indirect labor time, that is, along with the labor directly expended in the production of the commodity, the labor embodied in the machines and tools employed in producing it, the labor embodied in the machines and tools used to make those machines and tools, etc. Kantorovich insists, correctly, then, that the value of a commodity incorporates some components in respect of the capital equipment used along with labor time in producing it. But he goes beyond that.

Two issues have to be faced, corresponding to the two nonlabor members of the classical trinity of factors of production. When a linear programming problem is solved, it is likely to turn out that both capital and land have positive objectively determined valuations, and these have to be reconciled with the labor theory of value. Kantorovich handles both problems by the same device which is, unfortunately, nowhere stated very compactly. It amounts to valuing a unit of capital or land in accordance with the amount of labor time that can be saved, at the margin, by the use of a unit of that type of capital or that quality of land. For example:

In problems of the use of equipment the amount of use in the manufacture of a given product or in any operation must be taken into account by making an allowance for the hire valuation of the equipment. Its magnitude, equal to the saving of labour obtained from an additional unit of equipment in an optimal plan, is determined by all the actual conditions . . . (p. 85).

And again:

In solving problems of the use of natural resources which are more efficient but in short supply, their use must be determined by allowing for differential rent. The magnitude of the latter is determined by the saving of labour obtained from the use of these resources in the optimal plan (p. 99).

Furthermore, these imputed values (please forgive the bourgeois term) should be reflected in the prices of the commodities produced: "Consequently, the calculation of the rent should play an important role in questions of price formation" (page 99).

With these conclusions I can have no quarrel; the logic of linear programming (not to mention bourgeois economics) enforces them. But can the labor theory of value be extended this far? I maintain that it cannot or its major implication that exploitation of the workers is inherent in capitalism will be impugned.

Simply as a matter of doctrine, the concept that the value of anything is the amount of labor time that its possession enables the owner to save is not to be found in either Ricardo or Marx. It is much closer, indeed, to Adam Smith's concept that value is equivalent to a command over labor. It is closer still to the modern bourgeois, neoclassical view that the value of any productive instrument is equal to its marginal productivity, the only difference being the purely verbal one that Kantorovich has chosen to use labor time as the *numéraire* in terms of which to express the value of everything else. But who said what is not important; we are concerned with logical implications.

And the logical implication is this: If factors of production are valued in accordance with their objectively determined valuations, properly computed by Kantorovich's methods, then it will turn out, because of the principle of duality, that they absorb the entire value of the output. To be sure, the value of output will exceed the direct labor cost, it will even exceed the direct-plus-indirect labor cost. But the excess will not be due to capitalist exploitation or to the fact that workers can produce in a year more than is necessary to sustain them. The sustenance requirements of workers do not even enter into the computation. It will be due to the fact that the cooperating factors enhance the quantity (and thereby the value) of the output. Once these cooperating factors are credited with the values of their contributions, as Kantorovich recommends, no surplus value and exploitation remain.² It is because linear programming proves this so easily and clearly that bourgeois economic theorists are enthusiastic about it, Kantorovich also has good reason to be enthusiastic

² This argument abstracts from complications such as increasing returns to scale and indivisibilities, which Kantorovich also is content to ignore.

about it, but if this is the labor theory of value *Das Kapital* will have to be rewritten for it will not sustain the argument of that book.

In addition to expounding the economic implications of linear programming, Kantorovich includes a long chapter on the valuation of capital and the use of discounting. I do not have space to discuss this chapter except to note that on the whole Boehm-Bawerk would have approved of it. Kantorovich notes, for example, that in computing the labor-saving attributable to a unit of capital, labor saved in the future should be discounted in relation to labor saved in the present. "Such a reduction in the valuation of labour is, in actual fact, consistent with the statement that a rational expenditure of labour today enables one to obtain a much higher saving of labour in the future; and hence one must assign a higher valuation to a unit of labour for any given year than for the following one" (pp. 193-94).

The exposition throughout is in terms of artificial numerical examples which illustrate economic principles, but are too simple to even suggest the rationale and technique of linear programming computations.

Throughout this review I have dealt with Academician Kantorovich as a serious scholar who has offered a serious book, as is due a man of his eminence and accomplishments. But I should not be candid without confessing that at times I found it hard to believe that Kantorovich so seriously misconstrued the implications of the powerful technique that he has done so much to advance. It appeared to me that he was asserting the Marxist orthodoxy of the linear programming in the hope of reducing some of the resistances to his recommendations. This is the light that the book throws on the state of economic thinking in the Soviet Union.

ROBERT DORFMAN

Harvard University

Soviet Economic Processes. By EDWARD AMES. Homewood, Ill.: Richard D. Irwin, Inc., 1965. Pp. 257. \$3.00 (college price, soft cover).

The aim of this book is to provide "an explanation of Soviet producing enterprises and the nature of the general economic equilibrium in the Soviet system." The basic building blocks for such a task are a microeconomic theory of the Soviet firm and an input-output type model of the financial flows between groups of institutions. From a set of relatively simple assumptions a series of models are constructed, and a set of testable hypotheses is derived. Relevant institutional materials are presented to give flesh to the models and to show the relevance of some of the conclusions. Although many objections can be raised against the various models, it is the most original treatment of the Soviet economy which has appeared in some years.

The microeconomic theory of the Soviet firm is built on the assumption that such firms are output maximizers, subject to the restraint that total revenues must be equal to, or greater than, total costs. From this assumption the author derives a series of propositions about the relation of average and marginal costs, the optimal use of productive factors, and the response of Soviet enterprises to changes in input or output prices. The role of enterprise plans is introduced through the concept of multiple prices in an interesting way. Re-

straints on the use of inputs which are placed on the firm by the plan can be shown to be a type of multiple-pricing arrangement. Similarly, the differential treatment of "above and below plan profits" can also be interpreted as a type of multiple pricing. The author then shows how multiple-pricing phenomena can still be handled within the previous models so that it is possible to analyze the joint roles of plans and prices in determining the level of output and the use of productive factors. Although the author also constructs a general equilibrium model from this basis, he stops short of proving that such a system is determinate.

The major advantage of such an approach lies in the attempt to show rigorously the interrelations between prices, plans, costs, and plan fulfillment. The author frankly recognizes that his microeconomic models are oversimplified, especially because of the neglect of the different complex incentive schemes, of risk factors, and of the interrelations of this year's plan fulfillment with next year's plan. But intensive examination of the implications of his models allows the author to discuss a number of important and hitherto neglected facets of the actions of the Soviet firm. Moreover, although the propositions generated from the models can be found scattered throughout the Western literature, the use of the models permits the logical interrelationships of these propositions to be more easily perceived.

In the chapters dealing with Soviet macroeconomics, the author starts with a simple four-sector (households, state budget, retail outlets, and enterprises) schema, defines a matrix of monetary flows between these sectors, and, with the assumption of certain fixed coefficients defining these monetary flows, derives a series of propositions about the relations between prices and output. Then, by assuming that the Soviet state is a monolithic entity with a real-valued preference function, he derives a series of welfare economic propositions about planning from a model related to this flow matrix.

In the macroeconomic area I believe that the advantage of the author's approach lies less in the formal models which are developed than in the analysis of the factual and institutional materials which must be covered. By looking at the Soviet economy as a series of financial flows, the author analyzes a series of institutions and the interrelations between these and other institutions which are seldom discussed in the Western literature on the Soviet economy. I found his discussion of the construction enterprises and of the investment process particularly informative.

However, the usefulness in explaining Soviet reality on the basis of certain of the models is often not very clear. For instance, in the discussion of financial flows, the author assumes certain fixed coefficients relating financial payments through the state budget and other output flows. But these "coefficients" are really quite variable and are the result of conscious policy decisions. Of course, the author rightfully points out that open input-output models are more useful in looking at Soviet reality, but he spends relatively little space analyzing these. On a different level, assuming the state to be a monolithic entity and positing some real-valued state utility function allows a number of interesting formal propositions of welfare economics to be made, but does not seem directly related to the stated purpose of the book.

Such a macroeconomic approach also poses a number of aggregation problems. For instance, relating output and plan goals provides insights on the microeconomic level. But applying such a function on a macro-level, especially when the interrelations of enterprise plans and capacity restraints are not fully clear, raises a number of difficulties.

Aside from the macroeconomic and microeconomic models there are a number of fascinating analyses of a number of seldom-discussed problems. The author presents a series of novel notions about the relations between administrative tiers, span of control, volume of decisions to be made, and the effects of introducing a probability element into the execution of plans. He also presents a very thoughtful discussion of the interrelations between physical and financial planning.

Finally, it must be noted that although the book has a number of profound insights, the reader also discovers some disconcerting errors. Confusion between increasing short-run average costs and long-run decreasing returns to scale (pp. 116-17) vitiates a whole series of propositions, the validity of which depends on the size of a particular variable. Similarly, in a geometric demonstration about the effects of rationing (pp. 94-95), he neglects the effects of a different placement of indifference curves (which would lead to directly opposite conclusions from those derived). There are also several small factual errors (e.g., "adjusted world market prices of 1950" have not been used in intra-East Bloc trade since around 1955).

But none of these criticisms is meant to detract from the author's important contribution—the first full-scale rigorous attempt to present a general theory of the operation of the Soviet economy. Whether one agrees with the usefulness of the models or not, the author's provocative approach and skillful integration of theoretical and factual materials make the book extremely stimulating reading.

Money, Credit, and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

Development of British Monetary Orthodoxy, 1797-1875. By FRANK WHITSON FETTER. Cambridge: Harvard University Press, 1965. Pp. xiv, 296. \$7.25.

This is a book in a generation. It surpasses in scope and documentation the comparable chapters in Viner's long-distinguished *Studies in the Theory of International Trade*, and it integrates a lifetime's flow of scholarship which has made Frank Fetter supreme in his field. It is most carefully constructed, with a terse, direct style that is occasionally arresting.

Fetter seeks to explain the formation of pre-1914 monetary orthodoxy, the influence of which persisted until the 1930's. It comprised gold monometallism with a fixed parity; a central bank, oriented to convertibility; and control of notes but not of deposits. This search involves instructive explorations of the history of theory, of monetary legislation, and of financial institutions. Thus,

the opening chapter on the monetary scene in 1797 is followed by chapters on inconvertibility, resumed gold payments, and the new gold standard of 1819; three central chapters discuss the consolidation of the gold standard, and legislative reforms; finally, two closely argued chapters scrutinize the acceptance by the 1870's of "the Bagehot principle" of acting before instead of after a crisis.

The strength of orthodoxy was its practical appeal; its ultimate weakness was its marshy intellectual base. Fetter pinpoints this in aptly suggesting that the appeal of Say's Law "probably was the result rather than the cause of monetary thinking"; the orthodox accepted its support for policies based on hostility to aristocratic government and to a myopic Bank of England. The gold standard was a deadly illustration. Although it had existed *de facto* for eighty years when suspended in 1797, eighteenth-century economists scarcely recognized the implications of monometellism; worse, their nineteenth-century successors used "economic theology rather than economic analysis" to justify the gold standard. An important explanation of this, Fetter might have stressed (he is obviously aware of it), was the infancy of professionalism, especially in economics, and the persisting English predilection for gentleman amateurism.

Orthodox adjustment theory muddled price rather than income effects. (Fetter discovers but one attempt at statistical verification.) The money-prices link was regarded as long term; short-term monetary action was none the less believed, correctly on the evidence, to have price effects, on stocks of goods rather than on current production, and on commodity rather than on factor prices. This weakens assumptions of nineteenth-century price flexibility; its echo of modern "stop-go" economics is a commentary on Britain's slow progress towards monetary management.

Unquestionably orthodoxy was rigid, but does Fetter inadvertently blur the rigidity of its chief inspirer, Ricardo? He doubtless underestimated the consequences of restoring sterling's old parity in 1819, but does Fetter grant enough weight to Ricardo's claim in a speech of 1823 that his underestimate had been of the "unnecessary . . . mischievous operations" of the Bank of England in botching convertibility? Subsequently he quotes from the same speech Ricardo's assertion that he cared less about a particular parity than about securing some sort of fixed standard. This was *ex post* wisdom—the owl coming out at midnight.

Years earlier Ricardo had advocated deflation, which brought the old parity so near by 1819 that, as in 1925, a last heave was widely preferred to devaluation. On all decisive occasions Ricardo deplored clumsiness but opted for rate rigidity.

Fetter demonstrates that central banking before 1840 was "hardly more than a footnote" to post-1844 developments. He etches subtly and for the first time the delicately evolving relationships between government and central bank. Accurately sensing the social atmosphere, he stresses both the Bank's haughty devotion to public ignorance of its activities and its counterpart in the exclusive chatting "in the clubs, at the country estates, at the meetings of old Etonians, Oxonians, and Cantabrigians, and possibly at the Political Economy Club." Unfortunately, this section displays Fetter's one weakness:

his emphasis upon policy and upon the stabilization of monetary legislation bypasses substantial changes in the monetary system. Discussion of tension between Bank and money market is inadequate without mention of the 1858 "Rule" which estranged them, or of the increasing disproportion between their respective resources. Likewise, though rightly rejecting the arrogant "Englishman's moral burden" approach to gold standard management and to international lending before 1914, Fetter underplays sterling's role as a reserve currency; may he not thereby underrate the international significance of Britain's avoidance of open sterling crises between 1866 and 1914?

Does the apparent anomaly of restricting notes but not deposits nag Fetter excessively? Majority thinking tied deposits to the supply of "hard cash," and consequently favored a single, simple control. Moreover, stress on time deposits rather than checking deposits left a weaker case for interference with apparently voluntary *ex ante* savings than for protecting the involuntary and often helpless noteholder. In fact, the government protected small depositors through the trustee savings banks and later by the Post Office Savings Bank.

This masterly book deploys an enviable knowledge of a massive literature. Two points invite correction. Like others Fetter neglects *Protection to Agriculture* in discussing Ricardo's interest theory; and Jevons *did* publish a suggestion for a better (tabular) standard, in Chapter 25 of his *Money*.

Here is outstanding scholarship, definitive, and durable. Fetter has so thoroughly reorganized our view of monetary orthodoxy that much rethinking of hitherto received truths is in order.

L. S. PRESSNELL

London School of Economics

Government Securities Market. By IRA O. SCOTT, JR. New York: McGraw-Hill Book Company, 1965. Pp. xiii, 239. \$12.50.

Professor Scott has produced a highly informative, useful, and much-needed book on the dealer market in U.S. Government securities.

Chapters 1 and 2, which describe the composition and characteristics of government debt and the portfolio policies of the major investor groups, set the background for the description and analysis of dealer operations in Chapters 3-5. A strong feature of the background chapters (and Chapter 3) is the breadth of coverage and the fact that the author has brought together in one place detailed information on such technical matters concerning government securities as their terms and methods of issue, computation of interest, and tax characteristics.

Chapter 3 contains a description of the "Day-to-Day Operations of a Government Securities Dealer" from the vantage point of a professional economist who has (in his own words, but in a different context) "stood many times at a trader's side discussing complex questions of economic policy. . ." (p. 78, fn. 6). Scott covers some highly technical material—for example, in his treatment of how dealers make a market and the problems of financing dealer positions—with great expertise and in a highly exciting manner. The various phases of dealer operations are often described with, to say the least, a grand flourish. Not only do we see the mass of cold figures and computations that are essen-

tial to the firm's operations, but we also follow the trader as he "takes his lunch—bites of a cold sandwich and gulps of black coffee— . . . [and] takes dessert—tidbits of gossip and a spicy story from another trader . . . —while an itinerant bootblack shines his shoes" (p. 79).

The analytical core of the book is found in Chapters 4 and 5. In defining dealer performance, Scott states that the quality of a dealer's market is judged by the quantity of securities for which bid and offer quotations are firm and by the narrowness of the spread. Because of difficulties of measurement, however, the size of gross positions is used to measure market performance, since dealer positions tend to be larger when spreads are narrow and commitments are large. The determinants of position policy are classified in two categories, those affecting the expected return and those affecting the variance of that return. His discussion of the individual factors in each category is generally excellent.

Scott next constructs an abstract model of dealer position policy. The model is based upon the "expected-utility hypothesis, according to which the decision maker is assumed to maximize utility, which, in turn, depends upon a subjective evaluation of the function's moments" (p. 132). Because of the absence of information on dealer expectations, the model actually tested in Chapter 5 is one in which the independent variables selected serve as proxies for expected returns and the variance of expected returns.

Twelve dependent variables are used—aggregate long positions, short positions, and net positions in each of four maturity classes. Seven independent variables are used in each of the twelve cases. The empirical results are extremely difficult to summarize. In general, however, Scott seems to get his best results with a measure of the past rate of change of interest rates used as a proxy for interest-rate expectations (expected returns). This is especially true in the longer maturities. In addition, a measure of financing costs and the volume of dealer transactions, as an indicator of uncertainty, have some explanatory value.

In Chapter 6, the author considers some important questions of public policy largely from the point of view of the impact of these policies on the performance of the dealer market. On this basis, the Fed's bills-only policy receives good marks as it contributes to an improved market performance through the reduction of uncertainty. Included among the numerous suggestions for improving market performance are the extension of discount-window privileges to nonbank dealers, so as to provide them with needed financing facilities, and the pursual of a Treasury debt management policy aimed at a more regularly spaced maturity distribution of the marketable debt and a reduction in the number of issues outstanding.

Several critical remarks can be made. At times, Scott lapses into a somewhat uneven writing style and several technical passages are difficult to follow. Despite the 1965 publication date, considerable portions of the book clearly were written several years earlier, with the result that developments since 1961 or 1962 are treated only sketchily at best. For the academician, one of the most striking drawbacks of this slim volume undoubtedly will be its price—a healthy \$12.50.

These minor shortcomings should not be allowed to detract unduly from an otherwise excellent book. The footnote references are thorough, and a 46-page bibliographic appendix is quite useful. Scott makes a valiant effort both to define the technical terms used and to provide, where possible, useful illustrations.

In general, the book makes an important contribution to our knowledge of the dealer market—although, as Scott himself points out, the empirical results of Chapter 5 are only tentative, being based on weekly data for a 14-month period beginning in October 1957. As position data are now available for more recent years, it is hoped that others will be encouraged by Scott's work to undertake a more thorough empirical study of the factors affecting dealer position policy.

THOMAS R. BEARD

Louisiana State University

Public Finance; Fiscal Policy

The Logic of Collective Action—Public Goods and the Theory of Groups. By MANCUR OLSON, JR. Cambridge: Harvard University Press, 1965. Pp. 176. \$4.50.

The central thesis of this book can be stated in a series of propositions. An organization is a provider of some collective good to a particular public. In the nature of a collective good, no member of that public can be excluded from enjoying it. Hence any individual member of that public or group has no rational reason to join the organization voluntarily and to contribute to its costs of operation and supply. On the contrary, the rational individual will refrain from joining unless he is induced by sanctions or side benefits.

Mancur Olson recognizes that if this thesis is right it would seem to apply to organizations both large and small, and he inquires whether this is so. He finds that small organizations are often able to dispense with sanctions and inducements, and he explains this on the ground that when a member of a small group has a disproportionate interest in the collective good, the benefit he receives may be so large a part of the whole that he may be willing to pay the whole cost of providing it. Even in this case, however, the collective good will not be provided on an optimal scale, since its supply will be regulated by the satisfaction of the individual (or few individuals) paying the bill, and this is likely to be short of the point at which the group interest would benefit from the collective good—if only some were not so calculating as to try to turn it into a free good.

Hence the further conclusions that the larger the group, the less likely will be its organization, and the farther will it fall short of providing an optimal amount of a collective good.

"Some critics may argue that the rational person will, indeed, support a large organization, like a lobbying organization, that works in his interest, because he knows that if he does not, others will not do so either, and then the organization will fail, and he will be without the benefit that the organization

could have provided." But Olson argues that the analogy with perfect competition is apposite here: "in a large organization, the loss of one dues payer will not noticeably increase the burden for any other one dues payer, and so a rational person would not believe that if he were to withdraw from an organization he would drive others to do so."

The book suffers mostly from being overelaborated. It attempts to explain too much too simply, and tilts at too many analytical predecessors. The heart of the book is in the first chapter of 52 pages, and this is very much worthwhile. If the thesis is not as novel as the author perhaps believes, it has seldom if ever been stated so explicitly or so conceptually, and this is a genuine contribution. The remaining five chapters, which are applications or elaborations of the central thesis, add little and suffer by comparison.

It is easy to find points to quarrel with in this volume. A few examples should be enough to suggest the sometimes simplistic quality of the arguments. There is an underlying assumption that any participation in group action involves a cost, and hence an explanation is required as to how a latent group can be activated, since all its members, if rational, would refrain from joining in the expectation of getting a "free ride." Result: no organization, since in a large group those receiving disproportionate benefits are too few and the benefits too small a part of the whole to warrant their giving others the free ride which is hoped for. But what to Olson seems unlikely if not absurd—that some will work "free" for others—is sometimes the case; it is the activists and the cause-fighters who accept disproportionate expenses and may ask nothing much more than that latent members approve their initiative, that is, provide nominal (cost-free) support.

Exaggeration is involved in the assertion that exclusive groups (those sharing a collective good which is fixed in quantity, such as sales at a given price by an oligopoly) must be all or none. The author recognizes in a footnote that a noncooperating firm may not be able to threaten oligopoly collaboration because of its limited capacity or cost structure, but dismisses this as unimportant, despite the relatively few instances in which oligopolistic cooperation is 100 per cent inclusive. His interpretation of price warfare as an attempt to drive a rival or rivals from the industry ignores the significance of Fellner's quasi-agreement, under which not a reduction of "membership" in the group but acceptance of a joint code of behavior is the objective.

There is a tortured attempt to explain a differential function for the closed shop in small and large unions. The alleged nonoptimality of the level of provision of the collective good even in small groups rests on a shaky foundation: if a small number in a community have so strong a desire for a public park that they bear the whole cost themselves, who is to say that the community "free riders," who by hypothesis are less interested in parks, will not have their lesser interest fully satisfied by the park that the enthusiasts have provided?

These criticisms are not intended to demean the book's value but to indicate where that value lies—in a lucid if bald statement of the difficulties of securing individual support of collective objectives, rather than in the painstaking and sometimes unconvincing elaboration of the core thesis. Olson's book is a

significant and valuable contribution to the economist's attempt to come to grips with organizational problems.

NEIL W. CHAMBERLAIN

Yale University

Fiscal Neutrality Toward Economic Growth—Analysis of a Taxation Principle. By EDMUND S. PHELPS. New York: McGraw-Hill Book Co., 1965. Pp. ix, 113. \$6.95.

This essay considers the question whether it is possible by fiscal and monetary policy both to maximize social welfare in a Pareto-optimum sense and at the same time allow the rate of economic growth in the private economy to be determined by the free choice of consumers through the market mechanism, thereby avoiding the need for a politically-determined growth policy. More loosely, the question is: Could society be assured full employment and the kind of income distribution it desired if the government took pains to be neutral with respect to the rate of economic growth (the latter being assumed to be a function of investment)?

The author argues that a combination of such fiscal neutrality and maximum welfare is theoretically conceivable both in a barter economy and in a modern money economy with a central bank, public debt, etc.—though only under highly restrictive assumptions. A major one of these is that taxes are confined to lump-sum, once-for-all kinds that do not bias the market's choices among goods and services and that do not reduce the desire to work, save, or take risks—i.e., that do not have substitution effects. But except for nonrecurring or at least unpredictable capital levies and head taxes, it is difficult to think of significant examples of lump-sum taxes nor does the author cite any. It is even more difficult to regard them as offering continuing sources of substantial government revenues without early sacrifice of their lump-sum character: a recurring capital levy, for example, would soon function much as a tax on income from property, and even as a comprehensive income tax if the capitalized value of income from personal services were included in the tax base.

Other important assumptions are that the information, skills, and political organization are available to permit government agencies to design the mix of fiscal and monetary policies perfectly, that such policies are instantaneously effective, that all markets are perfectly competitive, that there are no external economies or diseconomies in consumption and production, and that there is no conflict between the welfare of a present and subsequent generations.

Although the author early concedes that these assumptions are far from the facts, he devotes much of the book to showing how fiscal neutrality might nevertheless be approached in practice by a combination of budgetary, debt, tax, and monetary policies designed in part to compensate for unneutral taxes and other departures of the real world from his model.

In this process, he makes a valuable contribution to the theoretical literature by examining various circumstances in which a balanced budget, the existence of a public debt, debt-financing by government of capital outlays, etc., might be neutral or unneutral with respect to economic growth; and by showing how some of the well-known criticisms of *laissez-faire* capitalism with re-

spect to economic growth, such as underinvestment by reason of greater private than social uncertainties and risks, apply to modern mixed economies, and how the grounds for such criticisms might be reduced by fiscal and monetary policy.

Despite his recurring advocacy of the merits of a neutral fiscal policy and the pains with which he examines the theoretical possibilities of achieving it, he reluctantly concludes in the end that "there is no hope for the optimality of so simple a policy as neutrality in a complex world," and that in such a world "there seems to be little merit in a policy of neutrality."

The tenor of these conclusions on the last page of the essay is curiously at variance with the previous stout defense of neutrality as at least an approximate goal. Moreover, since the essay's point of departure is a dissent from the views of Abba Lerner, Paul Samuelson, and others that an intelligent modern government must have a politically-determined growth policy in the sense of at least loose growth-rate targets, the essay's conclusions would seem to rob the dissent of practical significance. Nevertheless the essay is a stimulating one that fills a number of gaps in the theoretical literature.

The inclusion of this book in a series of "economic handbooks" merits the caution that much of the detailed analysis, though not the broad reasoning, is algebraic in form and presupposes more than a beginner's knowledge of economics.

Studies in Greek Taxation. By GEORGE F. BREAK AND RALPH TURVEY. Research Monograph Series No. 11. Athens: Center of Planning and Economic Research, 1964. Pp. 250.

This study is an outstanding contribution to the literature, both for its account of the Greek tax structure and as an addition to the all too scanty works on taxation in developing countries.

The book is in two parts, entitled, respectively, "Description" and "Analysis." Part I, however, is a good deal more than bare description, and Part II, which is mainly a study of particular taxes, contains a good deal of further description. The work ends with excerpts from incentive legislation for industrialization, which in variety and extension would appear to outdo most other countries.

After an account of the Greek (very centralized) constitution, Part I is occupied with a description of the components of the tax structure, which together amount to 22-24 per cent of the GNP. Well-chosen illustrations of the working of particular taxes make this easy reading. (For instance the Stamp Duties on a particular transaction may require the licking of 40 stamps, amounting to some 1100 drs.)

The Greek tax structure is a fascinating medley of the modern and the archaic. The income tax was reformed some ten years ago and the profits tax more recently. Moreover, fairly adequate ways of taxing farmers have been devised, by means of a graduated personal tax (similar to that of East Africa) and a sales tax on certain farm products. These sensible taxes are, however,

accompanied by an incredible array of complicated little levies which are certainly not worth their keep.

The two outstanding peculiarities of the revenue structure are (i) the practice of assigning (earmarking) almost all revenues for particular purposes, not just straight, but with little contributions from different sources; (ii) the exceptional importance of social insurance contributions (a third from workers and two-thirds from employers). These contributions and the funds that administer them form 25 per cent of the activities of the government. There are some 200 separate funds, financed in part by small assignments (in the case of the farmers' O.G.A. very largely so, implying that townspeople pay most of the farmers' insurance). Since there is no general policy in respect of the funds, fortuitous surpluses from some of them are a continuing temptation to extraneous expenditure. More serious, "the figures reveal neither the total revenue collected by the central government, nor that part which is available to be spent by it."

Like other Mediterranean countries, Greece relies heavily on taxes on outlay: for 69 per cent of the revenue, if social insurance contributions are excluded as being only partly tax. Of this revenue, customs duties are responsible for 22 per cent, general sales taxes for 23 per cent, and selective sales taxes for 55 per cent. The effects of excises and turnover taxes have also to be considered. In Table 4.3 (p. 134) an attempt is made to estimate the allocative effects of this aggregated taxation. Tobacco, alcohol, entertainments, and vehicle circulation are all highly taxed, well in excess of the industries' contribution to the GNP. At the other end of the scale such important industries as ship-building, building and contracting, newsprint, and fertilizers are very lightly taxed.

These differences are often due to discriminatory rates of turnover tax, an important (16 per cent of commodity taxes) but peculiar feature of the Greek tax structure. This is assessed on output less cost of materials so is not cumulative. Exports get very ample rebates at all stages. Lower rates in the Provinces and still lower in the Islands provide a fiscal incentive to decentralization. Owing to rebates and exemptions, revenue is mainly collected from some 3000 fairly large enterprises. Finally, the turnover tax is integrated with the income tax, which together with inheritance and gift taxes account for 13 per cent of the revenue (17 per cent if social insurance contributions are excluded). As mentioned above, income and profits taxes have a relatively modern structure and are well integrated. But assessments and collections are badly eroded. After no more than ten years, there are 423 causes of exemption from the income tax.

The last part of the book is concerned with priorities for reform, the need for most of which would be readily apparent if more statistics were available. Thus a family expenditure survey is needed to determine the incidence of dependents' allowances and of deductions for medical and dental expenses. In respect of commodity taxes "nobody knows anything about the joint pattern." Effective compensatory finance would therefore be impossible.

The most interesting reform suggestion is concerned with direct taxes: income tax, capital gains tax, and a tax on net wealth. Marginal rates of income

tax are high to the point of disincentive, especially at the point of initial liability. On the other hand, average rates are low, so that the whole course of the tax is little more than proportional. The suggestion is that this should be frankly recognized and the progressive element of the tax structure transferred to a capital gains and wealth tax. Apart from the limited effectiveness of a capital gains tax in a situation where most of the gains will be made in the difficult valuation field of real estate and not on the stock exchange, the second suggestion calls for very careful scrutiny.

Chapter 6 of Part II, where plans for a net wealth tax are set out, is of exceptional interest, if only because it is a valiant attempt to think up methods of valuation in semideveloped conditions. For real estate three methods are suggested: (i) future discounted earnings, (ii) original cost less depreciation, and (iii) contemporary sales values. It is suggested that in respect of the last (which clearly begs the fewest questions), the government might deliberately increase the volume of sales in order to widen the market. Where equipment is an important element in the value of the asset, it is suggested that total values can be checked against income tax returns, capitalized at an appropriate rate of interest. (One wants to know both whether income tax returns would stand up to this responsibility and how the appropriate capitalization rate would be chosen.) The difficulty of valuing consumers' durables would be bypassed by substituting a special excise (10 per cent rate of this corresponding roughly to a 1 per cent rate of wealth tax). To deal with intangibles all companies would have to furnish lists of shareholders, with their several interests, and banks the balances of their customers. Finally human capital might be included by requiring each taxpayer to capitalize his expected stream of earnings. (He would be supplied with tables for the purpose.)

It is an ingenious program, but its practicability is, to say the least, somewhat doubtful. It should be borne in mind that the much vaunted wealth taxes of the Teutonic countries turn out on examination to have become eroded to little more than taxes on real estate, whatever the original intention. (See the Symposium from countries practicing them in "Public Finance" 1960.) If the Greeks have allowed their income tax to become as eroded over ten years as has happened, there seems small hope that the much more complicated tax on net wealth would fare any better.

It is claimed that the net wealth tax would lead to a better use of resources, especially of underused land and the maintenance of excessive inventories. But surely there are simpler and cheaper ways of attaining these ends. A firm determination to abolish most of the exemptions in the income tax and an increase in the number of steps in marginal rates would go a long way, if they were backed up by better administration. The greatest need in Greece, however, would seem to be the introduction of a comprehensive annual budgetary review which would reveal on the one side the total fiscal outlay of public bodies and on the other give an account of the total tax pool, with a drastic reduction in assignments, so that the interrelation of tax incidence and effects could be estimated.

Patterns of Public Sector in Underdeveloped Economics. By IGNACY SACHS.
New York: Asia Publishing House; Taplinger, Distributor, 1964. Pp. x,
196. \$7.75.

This revised and translated version of a book published in Poland in 1961 is devoted to assessing the effectiveness of alternative types of government policies for carrying out economic development in the contemporary underdeveloped world. Three main lines of argument are developed: (1) an explanation of why there is a large development gap among nations; (2) an evaluation of the relative productivity of the private capitalist and public sectors in generating accumulation; and (3) a comparison of two particular types of public sector patterns. In the first of these, called the Japanese type, the state nationalizes social overhead production and assists in development financing through such devices as state investment banks, but does not extend economic planning beyond fiscal policy and sectoral investment policy, and encourages both the import of foreign capital and the development of an indigenous capitalist class. In the second or Indian type the government nationalizes a number of strategic industries so that public sector growth will be higher than that of the private sector, thereby braking the power of monopoly capital, while the economic independence of the country is fostered, and comprehensive planning, physical as well as financial, is practiced.

The results of the analysis are that: (1) underdevelopment around the world has common origins and causation in the interaction between capitalism and the colonial systems; (2) classical patterns of development are not open to currently underdeveloped countries because of the very different world market conditions these countries face than did their predecessors, and because of the lure of a short cut to development provided by the experience with socialist industrialization; (3) the economic and political structure of underdeveloped countries makes high rates of private accumulation virtually impossible, so that the government must take the lead in mobilizing resources if there is to be rapid growth; (4) state capitalism can thus be a relatively progressive phenomenon provided the government recognizes and accepts the role it must play in development; (5) whether the Japanese or Indian type will be chosen by such governments depends essentially on the relative political power of the native bourgeoisie and the forces of social democracy. To these conclusions are added value judgments, as Dr. Sachs calls them (apparently because they are not defended in this work), to the effect that the Indian pattern should produce a higher growth rate than the Japanese pattern, that the Japanese pattern can never be wholly successful, and that the only really effective solution is neither of these but the socialist pattern.

Of the three main lines of argument the first certainly gets the weakest treatment, being well below the standard for this genre set by, say, Paul Baran. The comparison of the two government policy approaches contains a good deal of stimulating comment on interest groups in underdeveloped countries. Unfortunately Sachs has not succeeded in finding a country that actually practices the Indian pattern. Certainly India does not, as he points out. One is left with the impression that there is a good reason for this, though Sachs does not discuss it explicitly. Any attempt to try the Indian pattern creates strong

resistance from the soon-to-be-expropriated capitalists, leading to political tension and either revolution or counterrevolution, that is, very roughly, a switch either to socialist development or to the Japanese pattern. Perhaps it is in this sense that the Indian pattern is more progressive than the Japanese, rather than, as Sachs implies, because it is more productive of growth; but that is a matter for the reader's political tastes to settle.

Probably the most interesting thing about this book is the fact that it represents a fairly serious attempt to develop for contemporary underdeveloped countries an analysis of economic interest groups and their political and economic impact, in the tradition of Marx's "Class Struggles in France," but without the invective. The native bourgeoisie, if not foreign capital, are granted in principle the ability to act in ways that foster development, and a substantial part of the book (Chapters 4 and 5) is devoted to assessing the circumstances under which state policies can be made consistent with the interests both of development and of the bourgeoisie. Though many readers will find the arguments naïve, Dr. Sachs's work nonetheless represents a further step toward more effective communication between Marxist and non-Marxist economists. If the former could profit from a more extended use of the analytic and methodological apparatus of contemporary Western economics, the latter could no doubt profit by following Sachs in taking on occasion a broader look at the social and political context in which their work finds its application.

BENJAMIN WARD

University of California, Berkeley

Problems of Tax Administration in Latin America—Papers and Proceedings of a Conference Held in Buenos Aires, Argentina, October, 1961. Baltimore: The Johns Hopkins Press for Joint Tax Program: Organization of American States, Inter-American Development Bank, Economic Commission for Latin America, 1965. Pp. x, 574. \$10.00.

This book, finally published after what seems a rather long delay, contains nine papers, together with a summary discussion of general issues. A useful feature is the publication of extended comments by Latin American fiscal experts, based on prior reading of the papers. These comments, together with the remarks of the discussants, bring into focus the gulf that inevitably exists between the preoccupations of North American experts, whose sophisticated analysis of administrative problems relates to a mature economy, and the immediate problems confronting most of the Latin Americans to whom the papers are addressed. A further dividend to the reader of these comments is the opportunity thus provided to form his own conception of the present state of administrative efficiency in various Latin American countries as seen through the eyes of the country expert, and to estimate the likelihood that recommended changes in procedures will soon be accepted. This information is not conveyed in the major papers, which are (understandably) closely geared to the particular competences of each speaker.

Most of the papers deal with technical problems of tax administration, but several concern themselves with broader questions of taxation and the charac-

teristics of particular taxes. Richard Musgrave discusses the problems of estimating the distribution of the tax burden. The nexus between Musgrave's study (which indeed devotes several pages to specifically Latin American problems) and tax administration is that a high standard of administration is a precondition of dependable studies of the distribution of the tax burden. John Due summarizes the problems of administration of sales and excise taxes. Both he and his commentators limit themselves to a general, rather than a "Latin American," approach to the question. Lyle Fitch deals with concepts and administration of taxes on property, and his commentators, as well as the discussants, devote attention to relating general considerations to specifically Latin American problems. In general, the discussants throughout the Conference show an especially lively concern for relating principles to local problems.

The rest of the papers are closely geared to the title of the book. Joseph Crockett discusses Latin American difficulties in tax administration, difficulties that make familiar reading to anyone who has had the opportunity to visit a Finance Ministry in any Latin American country. These are limited enforcement powers, inadequate supervision of the taxpayer, prevalence of noncompliers, complicated tax forms, too much faith in audit as contrasted with a full investigation of the returns selected for examination, and so on. In a comment, Mr. Piedrabuena points out that a training school for tax personnel was already functioning in Chile in 1961, under collaboration between the International Cooperation Administration and the U.S. Internal Revenue Service. A useful addition to the book would have been a statement of the substantial progress that has been made by these missions in other Latin American countries as well since the date of the Conference. The reviewer has had the opportunity to observe the dedication of the IRS people at work on this task in Lima.

An interesting paper by Marius Farioletti, Assistant Director of the Planning and Analysis Division of the IRS, is concerned with "Statistical Records for the Management and Control of Tax Administration." Useful advice is given on the rules-of-thumb that should be followed by administrators occupied with developing a system of records, and although reference is almost entirely to the problems as they are met in the United States, they are problems that tax experts in less developed countries soon will want to be thinking about. He stresses the nature of the "tax administration gap" (pp. 141ff.), and its components, as well as the costs and advantages of partially closing it.

Stanley Surrey discusses automatic data processing, rightly stressing the extent of the preliminary work that must be done before ADP can be introduced. A commentator from one of the smaller countries interestingly suggested that some of them might have to *share* a computer. Chadwick Haberströh deals with trends in management technique, stressing that a problem in Latin America is the attempt to impose impersonal tasks on organizations "while the matrix of their society remains person-oriented" (p. 226). Attention is called to the advantages of the "flexible, task force style of administration" (p. 235). Incidentally, Haberströh deplores limiting attention to the measurement of tax evasion (p. 241), and indicates the need for consideration of other

administrative functions as well (among them, ways in which the administration itself might improve on the equity treatment of taxpayers). Accounting and auditing procedures are discussed by Charles Taylor, and further discussion of controlling income tax evasion is provided by Oliver Oldman.

Throughout much of the volume run two themes. One is that any nation tax system must be related closely to economic and political institutions and to the tax morale of the public. The other is that the equity and effectiveness of a nation's tax system are likely to provide an index of the efficiency in general. Perhaps it may be suggested that another contribution to effective administration would be to limit the extent of use of tax incentives to attract industry and to stimulate investment which are often of doubtful effectiveness in any event.

International Economics

Reforming the World's Money. By SIR ROY HARROD. New York: St. Martin Press, 1965. Pp. viii, 181. \$5.95.

Monetary Reform and the World Economy. By ROBERT V. ROOSA. New York: Harper & Row, 1965. Pp. 1x, 173. \$1.95.

Both of these books stress the need for international monetary reform. They differ, however, about the immediacy of the need. Sir Roy Harrod emphasizes that the succession of near-crises in major currencies in the early 1960's mean that there is currently a large shortage of reserves. Robert Roosa, in contrast, believes the system has performed reasonably well and that negotiations are necessary to provide for the increases in reserves necessary to finance growing trade and payments. Roosa has been a prime mover in negotiating new financial arrangements—the General Arrangements to Borrow, the currency swap among central banks, the new U.S. Treasury securities denominated in foreign currencies ("Roosa bonds"), and in devising "rescue packages" for foreign currencies in distress (the pound, the lira, and the Canadian dollar); it would be unexpected if he indicated that the existing set of arrangements was seriously lacking in its ability to meet current needs.

Harrod pronounces the *ad hoc* arrangements set up in the last few years excellent, but he doubts they can be enlarged and formalized to the extent necessary to finance protracted payments imbalances. Roosa's view of the immediacy of the need for reform appears conditioned by his recent experiences negotiating with foreign central bankers. The key words for Roosa are cooperation, confidence, stability, sovereignty, and flexibility. Harrod challenges the central banker's view of the world: "The trouble is that the training and habitation of central bankers is to be pragmatic and to move step by step. The distrust ideas of a general character, and this way may be wise in the normal run of things, since it is quite correct to think that the most general ideas are dangerous." But for Harrod, obtaining the desired increase in reserves falls outside the normal run of things. Harrod wants to revive the atmosphere that

prevailed at Bretton Woods and suggests that this might be done by demonstrating the costs of a generalized reserve shortage in terms of foregone growth.

The Roosa volume, an expansion of the Elihu Root lectures in 1965, states the conditions for monetary reform and provides a comprehensive catalog of the possible ways to create new international reserves. The essential conditions include maintenance of the \$35 gold price, fixed exchange rates, and a continued U.S. role as world banker. He suggests ways to improve the functioning of the system short of reform—partly by the expansion of the *ad hoc* arrangements developed in the last several years and partly by greater use of IMF financial resources, made possible both by an enlargement of IMF quotas and easier access to foreign currencies in the Fund. On the reform agenda, Roosa proposes creation of a new asset ("The Fund Unit Account") within the IMF structure; this asset would be similar to the Composite Reserve Unit proposed by Edward M. Bernstein, and would supplement holdings of dollars, sterling, and other assets in international reserves. Roosa suggests rules to be used in determining which countries can acquire such assets initially and which countries must accept them in settlement of imbalances, and in what amounts. He also proposes creation of new secondary reserve assets, in effect, long-term "Roosa bonds," to be transferred between central banks. Roosa's theme is that there are a number of ways to create assets to meet the need for reserves, and it is self-defeating to discard any possible ways. Reserve needs can be met best by holdings of gold, dollars, sterling, and other currencies; by central bank currency swaps; by long-term and medium-term loans between central banks; and by claims on the IMF in the form of Fund Unit Accounts, and larger member-country drawing rights.

Harrod stresses that since the adjustment mechanism works slowly with fixed exchange rates and since flexible exchange rates would lead to international monetary chaos (a view shared by Roosa), a large increase in reserves is needed if direct restrictions on international payments are to be avoided. Much of the needed increase in reserves could be met through a world-wide increase in the price of gold. (Roosa wants to maintain the \$35 gold price, but his argument appears directed largely against a devaluation of the dollar in terms of other currencies rather than against a devaluation of all currencies in terms of gold.) Harrod explores the potential of mutual currency support arrangements and deems them much more useful to the United States and several other countries with high international credit standings than to the rest of the world. He argues that it is time for a review of the IMF Articles of Agreement, since they were hastily drafted in an atmosphere dominated by the prospect of continued European inconvertibility. Harrod examines a variety of ways to gear the IMF to meet reserve needs better and recommends that quotas should be enlarged, either on a once-and-for-all basis or on an annual and automatic basis, and that the Fund should be empowered to make investments in member countries so that their claims on the Fund will be increased. The dollar and sterling would continue to be held in international reserves, along with gold and the claims on the Fund.

Finally, and most importantly, Harrod wants to convert the IMF from op-

erating on an overdraft basis to operating on a deposit basis. Payments imbalances would be settled by changes in the entries in the Fund's deposit ledger. If, for example, Great Britain had a payments deficit, it might draw a sterling-denominated check on its deposit at the Fund, and present the check to the U.S. Treasury in exchange for dollars. The dollars would be used to support sterling in the exchange market. The United States would then transfer this check to the Fund. The Fund would debit the British account, denominated in sterling, and credit the U.S. account, denominated in dollars. Later the United States could draw a dollar-denominated check on the Fund to present to other countries to obtain their currencies to help finance a U.S. deficit. Harrod's proposal for reform is similar to Keynes's Clearing Union and Triffin's Central Bank in that payments imbalances would be settled by transfer of deposit claims on the Fund; it differs from their proposals largely in that each country's deposits in the Fund would be denominated in its own currency. And these deposits in the Fund closely resemble Roosa's Fund Unit Account. Roosa, however, advocates that the Fund still hold currencies of its members; in effect, he wants to create a deposit window within the Fund alongside its overdraft window, while Harrod wants to replace the overdraft window with a deposit window.

Harrod believes that the world's need for liquidity could be met by adoption of his proposals for reform of the IMF. An international central bank or a new international currency are not necessary; neither is an increase in the gold price.

The major difference between Harrod and Roosa is not in the choice of techniques for generating new international reserves, but rather the disagreement on the tests for the adequacy of reserves. Both acknowledge the relation between the process of adjustment to imbalances and the need for reserves to finance imbalances. Neither, however, really specifies the nature of this relationship. When Roosa suggests that the recent rapid expansion in world trade in recent years denies a reserve shortage, he ignores the heavy emphasis on restrictive measures that are increasingly characteristic of policies for balance-of-payment adjustment. Harrod views the several recent near-crises in the system as evidence of the over-all shortage of reserves; these crises, however, may reflect inadequate efforts to achieve payments balance on the part of countries with large persistent deficits, rather than a shortage of reserves available to the world.

The core of the reserve adequacy issue involves the relative obligation on countries with payments deficits and those with payments surpluses to take measures to reduce the imbalances. Harrod believes that adjustment to imbalance should consist largely of price rises in countries with payments surpluses; reserves must be adequate to finance the imbalance until the adjustment occurs. For Harrod, growth, unrestricted imports, and larger reserves are preferable to price stability, import restrictions, and smaller reserves. Harrod challenges the central bankers' view that the shortage of reserves provides a restraint on inflation in the countries with payments deficit. From the view of central bankers in the surplus countries, however, a reduction in the imbalance, whether attributable to deflation, devaluation, or import restrictions by the deficit countries, reduces the size of external inflationary pressures. But if, as

Roosa suggests, the creation of reserves depends on agreement among central bankers, then the desire by surplus countries to limit external inflationary pressures forces the burden of adjustment on the deficit country. The resolution of this issue depends on agreement on how this burden shall be divided, and not on some abstract measure of reserve adequacy.

ROBERT Z. ALIBER

University of Chicago

Government Risk-Sharing in Foreign Investment. By MARINA VON NEUMANN WHITMAN. Princeton: Princeton University Press, 1965. Pp. xii, 349. \$8.50.

Professor Whitman has written a lucid and perceptive account of six programs that share the risks of foreign investment with private U.S. banks and business firms. The programs are the Investment Guaranty Program operated by the successive U.S. foreign aid agencies; the World Bank; the International Finance Corporation; the Inter-American Bank; the Export-Import Bank; and the Development Loan Fund, a separate U.S. government agency between 1957 and 1961 and thereafter a part of A.I.D.

Each is assessed against a single criterion—its direct participation in the risks assumed by private capital. It is this criterion that gives the study its focus and its interest. The results are particularly illuminating in the case of the first five programs which were indeed designed to encourage U.S. private investors and traders to participate more actively in international economic life.

The concluding chapter offers tabular evidence on the relative importance of each program in stimulating the flow of private U.S. capital. The author concludes that none of them has been a meaningful catalyst, since two to four public dollars have been required to move each private dollar. This leads to a final observation that "viewed as a means of substituting private for public development financing on a large scale, the activities here discussed appear not only futile but actually dangerous to the national interest in their very inadequacy."

Analysis of each of the programs occupies the bulk of the book and represents its most satisfying contribution. The author reflects with precision and insight the evolution of policies and programs under the pressure of criticism and controversy. As an inexperienced U.S. government sought to bring its economic capacity to bear on the problems of the postwar world, much creative ingenuity was used to devise politically acceptable mechanisms. With time, misconceptions have been corrected and fears have been allayed. Both policies and legislative authority have been revised constantly—largely for the better.

The author has been particularly discriminating in selecting and soliciting relevant information. Her account will be valuable for those concerned with the inevitable changes in policies and administration. It should also be useful to businessmen interested in availing themselves of the ample opportunities for participating in the high returns that prevail on investment in less developed nations, while sharing the risks with their government.

The rest of the book is tantalizing. Material relevant to a number of current

policy issues is presented. However, even where the issues are discussed directly, the evaluation is incomplete or inconclusive. Should the proposed 30 per cent tax credit be enacted and the extended risk-guaranty program substantially expanded? Both proposals have been debated for some time and A.I.D.'s Advisory Committee on Private Enterprise in Foreign Aid has recently recommended their adoption. The author discusses both but stops short of a full appraisal. She also suggests a functional reorganization of U.S. bilateral programs, separating them according to their role in promoting capital flows. The same criterion might fruitfully be used to establish a division of labor between the World Bank and the bilateral aid programs or between the World Bank and the Inter-American Bank. It is these latter organizational problems that currently occupy the center stage.

The nature of the complementarity between public and private capital flows is treated narrowly. The book's preoccupation with the direct participation of private capital in the operations of the agencies under review stimulates questions about the indirect effects on private flows of foreign aid using public funds alone. The study notes the balance-of-payments problems created for developing nations by debt service requirements. If it were not for government grants and soft loans, would such developing nations as Brazil, India, and Turkey have been able to maintain the spotless repayment record of borrowers from the World Bank? Would private investors, U.S. and European as well, have been able to repatriate earnings and capital to the extent they have? Do such service requirements increase the need for government aid or, as is commonly argued, do private capital flows decrease aid requirements? Professor Whitman's study has the merit of provoking such queries.

It may well be that the principal "risk-sharing" contributions of the U.S. government emanate from the indirect effects of its foreign aid programs. Easing foreign exchange shortages facilitates service on private risk capital and the known preference of the U.S. government for private capital movements assures reasonable treatment of private risk-takers by most recipients of U.S. aid.

JACOB J. KAPLAN

George Washington University

Economic Aid and International Cost Sharing. By JOHN PINCUS.
Baltimore: The Johns Hopkins Press, 1965. Pp. xvii, 221. \$6.50.

This book, originally a Report of the Rand Corporation to the Department of Defense, deals with the need for more foreign aid, the problem of measuring the "aid" in foreign aid, the task of sharing the costs of foreign aid among donor countries, and the prospects for giving aid through commodity agreements.

After a brief review of "import gap" analysis, John Pincus concludes that although they cannot be precisely measured, the foreign aid requirements of the less developed countries by 1975 will increase from present levels by at least \$5 billion a year, net of debt servicing payments, if the less developed countries are to achieve per capita income increases of 2.5 to 3.5 per cent a year. This represents a large increase over present aid levels. How should the

costs of this large increase in foreign assistance be shared? And what form should the assistance take?

To allocate fairly the cost of foreign aid, one must first decide how to measure it. Pincus strongly deprecates the widespread practice of indiscriminately adding together cash grants, commodity grants, long-term loans, and medium-term export credits to reach a total level of "aid." He argues that commodity grants should be valued at world market prices, not at artificial support prices as is now done for some P.L. 480 shipments, and that loans should be entered minus their discounted future value, not at their nominal value. Rough calculations, using national interest rates to discount loan repayments, show that a nominal level of aid amounting to \$7.8 billion from all donor countries in 1961 shrinks to \$4.8 billion if the two indicated corrections are made.

Pincus argues that the benefits of this foreign aid to donors are too diffuse and too unmeasurable to offer a satisfactory criterion for cost sharing. He is thus driven to emphasize the donors' ability to pay, which he discusses in terms of total GNP, GNP per capita, level of unutilized productive capacity, balance of payments position, and availability of surplus agricultural production. He concludes that any search for an ideal cost-sharing formula will be will-o-the-wisp, but suggests that an ability-to-pay criterion based on GNP corrected for national differences in purchasing power offers the most fruitful starting point for negotiations among donor countries.

In correcting GNP for purchasing power differences Pincus erroneously follows the current vogue. The temptation to correct national income for differences in national purchasing power is a strong and a natural one for anyone who has experienced the large variation from country to country in how far he can stretch his consumer dollar. But in spite of its intuitive appeal, this correction is not warranted for cost-sharing purposes. With the free movement of goods, prices of traded commodities will not differ greatly from country to country. For competitive economies intercountry differences in the prices of services and nontraded goods will thus reflect intercountry differences in the opportunity cost of these goods and services in terms of traded goods and services. Ability-to-pay cost sharing should therefore be based on national income at national prices converted at equilibrium exchange rates, not at "purchasing power rates" computed on the basis of some bundle of consumption goods. Adjustments are warranted only if official exchange rates differ from equilibrium exchange rates or if there are marked deviations from competition in product or factor markets.

But this is merely a technical point. As Pincus makes clear, any formula for cost sharing can only provide the starting point for hard and basically political negotiations, except in those few cases—such as the Universal Postal Union or the General Agreement on Tariffs and Trade—where the sums are small and can be reasonably based on some indicator of benefits.

Pincus is not optimistic about the prospects for increasing aid in its present forms by the amounts he believes will be required. He therefore examines in some detail the possibilities for using international commodity agreements as a vehicle for transferring resources to the less developed countries. He concludes that only five commodities—coffee, cocoa, tea, sugar, and bananas—offer seri-

ous possibilities for transferring resources through price-raising international agreement; other commodities either have close substitutes produced in developed countries (oilseeds, rubber) or are consumed mainly by LDC's (rice). But on Pincus' estimates (the method for reaching them is not satisfactorily described, making them difficult to evaluate) these five commodities offer the LDC's in 1971 only \$900 million more than they would otherwise receive from exports. Moreover, there is no assurance that these gains will go to the right countries (Pincus points out, however, that over half the benefits will flow to Latin America) or, more important for development, that they will accrue to the right groups within each country. Capturing these gains for development presumes an adequate fiscal system, often sadly lacking. It is probably more likely that capital flight will be financed with high commodity receipts than with direct foreign assistance. Finally, higher commodity receipts may encourage primary producers to maintain overvalued exchange rates, and thereby impede the diversification of production which Pincus thinks is necessary. In view of the small potential gains and the great uncertainty of translating these gains into economic development, Pincus is perhaps more generous to price-raising commodity agreements than they deserve.

Pincus has written a useful book. He has summarized much existing material on cost sharing and has broken some new ground in the measurement of foreign aid. But unhappily he fails to find the key to raising aid by the \$5 billion he believes will be required. This will need a much bolder political approach to foreign aid legislation within the donor countries, based on a more experimental approach to aid giving. Aid must be justified for what it is, a program in social engineering as radical and uncertain as a moon shot is in aeronautical engineering, attended by great risk but also by great promise.

RICHARD N. COOPER

Yale University

African Primary Products and International Trade. Edited by I. G. STEWART AND H. W. ORD. Edinburgh: University Press; Aldine Publishing Co., distributor, 1965. Pp. xv, 218. \$7.50.

This volume brings together papers contributed by a number of economists from Africa, the United States, and Great Britain to an international seminar held in the University of Edinburgh's Center for African Studies in September 1964. The initial impetus for it grew out of studies undertaken in Nigeria and Ghana by members of the University's Department of Political Economy. Supported by the U.S. Department of Agriculture, their work was concerned primarily with the estimation of supply and demand functions. The United Nations Conference on Trade and Development then provided the inspiration for examining the specifically international problems of African agriculture.

The individual contributions differ widely in scope and method, but nevertheless combine into a balanced treatment of three main aspects of the primary producing sectors of Africa: their internal structure and functioning, their external effects on other sectors, and the policy influences to which they have been or may be subjected. The chapters are not explicitly subdivided

into corresponding sections, but they can easily be grouped along these lines without overmuch violence to their primary intent.

1. The core of the book consists of four papers on market structure—one by Robert M. Stern on the determinants of cocoa supply in West Africa, another on the coffee industries of East Africa by J. W. F. Rowe, a third on the difficulties of supply and demand projections by H. W. Ord, and the last by V. D. C. Wright on a determinant of the demand for food imports into West Africa. With the exception of Rowe's historical and descriptive work, these papers report on various attempts to apply statistical techniques to very crude data indeed. Some relationships do turn out to be statistically significant. But the main burden of the argument continues to rest on the evident need for improved data on which to base even the simplest of inferences.

2. The need for testing hypotheses is not thereby reduced, especially where the effect of specialization in primary products on other economic sectors is at issue. Recent challenges to conventional suppositions are taken into account at various points. Thus O. Aboyade notes Alasdair MacBean's claim that export instability has not noticeably retarded investment and growth in international comparisons, but he insists that overspecialization on a few commodities has nevertheless led to "capital distortion" by reducing the adaptability of the economy to changing conditions. Gerald K. Helleiner is similarly aware of B. F. Massell's doubts concerning the stabilizing role of export diversification, but he still finds cause to champion an international payments union to diversify what risks remain.

Helleiner also observes how insulated the export sector can be from the rest of the economy in Africa, even where it is based on peasant production. Thus the ratio of intermediate input purchases to the value of total production in Nigeria was only 2.6 per cent, for example, far short of the 31 per cent found by Chenery and Watanabe for Italy, Japan, and the United States. The percentage of output used as intermediate inputs in other industries was even lower, only 1.9 per cent, compared to Chenery and Watanabe's 72 per cent. Enclaves of this kind are therefore much more integrally part of the economies they supply abroad than of the countries whose territories they happen to occupy—even where very little foreign capital is involved!

3. The policy chapters are anticipated at the beginning of the book in a brief but useful survey of the prospects for African agricultural exports by J. A. C. Brown and by a discussion of the possible role of international organizations in the development of African primary products by H. M. A. Onitiri. Ian S. Livingstone then concerns himself in the last part of the book with rival arguments for and against government intervention in the marketing of domestic crops in Uganda and Tanganyika; Eric Clayton describes a linear programming study of policy alternatives to increase the efficiency of peasant production in Kenya; A. A. Suliman analyzes stabilization policies for cotton in the Sudan; and J. J. MacGregor explores the possibility of export diversification by developing timber resources.

Probably the most significant contribution to the book is Dudley Seer's paper on the special interests of Africa in international trade. He argues that

the oversupply of several primary commodities in world markets reflects the inability of Latin American countries to break into world manufacturing markets. If they were permitted entry there, "commodity markets would be vacated and Africa's share in these markets would grow." Even then, however, the projected increase in African export earnings would be insufficient for even modest development targets. Thus "trade not aid" is not in his judgment a slogan applicable to Africa. The need is rather for more trade and aid together, as the editors also point out in the introduction.

In sum, this book provides a balanced sampling of the kind of economic work being done on Africa. The pioneering character of the enterprise no doubt accounts for most of the deficiencies in its achievements to date.

The Balance of Payments: History—Methodology—Theory. By M. J. WASERMAN AND R. M. WARE. New York: Simons-Boardman Publishing Corp., 1965. Pp. xi, 481. \$10.00.

The first five chapters of this predominantly descriptive treatment of the balance of payments are historical and bring the reader from the bullionist period (dated as early as 1303) to the present. Developments within the United States and the United Kingdom receive extensive attention; several other countries receive lesser mention. The remainder of the book, seven additional chapters, is devoted to major facets of the balance of payments: nature, methodology, accuracy, measurement, reserve and exchange market policies, automatic disequilibria adjustments, and the international payments system.

The historical section focuses on the evolution of the concepts originally involved in the balance of trade, and later in the more inclusive balance of payments. Advances in methodology came slowly and sporadically. For example, it was not until 1911 that a comprehensive study of British foreign investments was made, while 1922 saw the first *official* U.S. balance of payments. Concepts changed slowly. At first the balance of payments was considered a statistical tool to be used in analyzing the international financial position of a country; it was not until after World War II that emphasis was placed on the extent to which domestically produced goods and services were transferred to foreigners, and on how the difference was financed. The International Monetary Fund's *Balance of Payments Manual* (1948) incorporated the then-current basic concepts and methodology; progress since then has been characterized more by minor improvements than by major changes.

Chapter 6 describes the minor differences between the U.S. and the IMF presentation forms, and points out the influence that the balance of payments has had on the other components of the nation's national income and product accounts. Chapter 7 focuses on the relative merits of linked and nonlinked source systems; Ceylon and the United States, respectively, are used as examples. The various methods of categorizing entries are described; one comes to understand why the errors and omissions account is so large and erratic. Woven into Chapter 8 are many of the recommendations of the Review Com-

mittee for Balance of Payments Statistics. If one wishes to discover how and where entries are made, and where they should be made (according to the Review Committee), this is the place.

Chapter 9 is especially well done. The authors describe the division of the balance of payments into substantive (above the line) and balancing (below the line) transactions and discuss the bearing that such classification has on the surplus or deficit. The authors do not avoid the relationship of deficit determination and policy considerations: an example is their treatment of the commonly heard criticism of the Department of Commerce's inclusion, *as a balancing item*, of the change in U.S. liquid liabilities to foreign *private* banks and other holders and the exclusion of their counterpart, U.S. private liquid asset claims on foreigners. *Official* short-term assets, on the other hand, are netted against official short-term liabilities. The rationale for this asymmetrical handling of official and private short-term assets and liabilities is inherent in the Department's "liquidity concept," which emphasizes the speed with which internationally invested funds can be used to defend the dollar. Alternative concepts are suggested, which call for different interpretations concerning which entries might be considered "balancing."

Chapter 10 describes how disequilibria may be settled through drawings on IMF rights, swap arrangements, prepayment of military exports, and the sale of Ruosa bonds. The special case of the reserve center country is discussed; a résumé of recent reserve policies follows.

In Chapter 11, which deals with the automatic adjustment of disequilibria, emphasis is placed on the elasticities of supply and demand in determining whether a flexible exchange rate will move within wide or narrow ranges. Some space is devoted to Keynes's interest-parities theory of forward exchange, and a reference is made to Paul Einzig's "dynamic" theory, but the reader is not treated to an explanation of the latter. The foreign trade multiplier is briefly discussed, especially in relation to the U.S. deficits of 1958-64. Multiplier effects on these deficits are said to explain, in part, the persistent unemployment and the relatively slow rate of growth in this country during that period.

In the final chapter, various exchange standards are discussed, and the modern era of international monetary cooperation comes in for brief scrutiny. It was disappointing to find so few of the many suggestions that have been made in recent years for the reform of the international monetary system, especially since U.S. balance-of-payments difficulties are probably largely responsible for much of this interest.

The bibliography is extensive and is divided into subject-matter groupings. The appendices contain reproductions of early English trade documents; selected U.S. balance-of-payments tables proposed by the Review Committee; consolidated balances of payments for several countries; and notes on interpretation. This reviewer can see no reason why this material should have not been placed in the main body of the book, where much similar material is found. There is an author index and a subject index, but no list of figures (only four in the entire book) and no list of tables (101 in all).

Readers looking for new contributions or sophisticated theoretical analyses will be disappointed in this book, but those interested in description and policy will find it a useful volume.

BYRON B. BROWN, JR.

Business Finance; Investment and Security Markets; Insurance

Business Finance—A Management Approach. By LOUIS K. BRANDT. Englewood Cliffs, N.J.: Prentice-Hall, Inc., 1965. Pp. vi, 633. \$9.75.

Manuscripts that achieve the preface goals should probably be considered a technical success. Acceptance of content and style is another issue. Professor Brandt has written a book "directed at undergraduate students seeking careers as business managers." Coverage is limited to internal financial analysis described in great detail. Repetitious references to decision-making implore the reader to utilize management techniques for planning precisely, executing carefully, and coordinating tightly short- and long-term policies. After many years of evolution away from finance texts emphasizing external, institutional viewpoints, it is surprising to find the same emphasis on definitions, forms, and lists of comparative advantages and disadvantages in a new book with the locale of analysis shifted to the internal environment.

The first 15 chapters on short-term topics are very similar to the first 17 chapters of a text written by Howard and Upton in 1952. Following a promising chapter on the relevance of financial theory, the reader is instructed in the construction of balance sheets and operating statements. Subsequent chapters describe techniques of controlling expenses, break-even chart analysis, ratios, pro forma statements, and cash budgets along with frequent admonitions to manage cash, temporary investments, receivables, and inventories for both liquidity and profitability. The first section is completed by a review of numerous sources of short-term financing. The decision to devote 15 chapters and 300 pages to short-term subjects and 15 chapters and 323 pages to the long-term section is typical of the thorough planning and organization of the author. The long-term material discusses the traditional topics of forms of debt and equity issues, capital structures, dividend policies, and special problems of changing ownership, recapitalization, reorganization, and beginning a new business. There is even a chapter on managing investment securities. Unfortunately, the good discussion of planning capital expenditures is followed by a very abbreviated coverage of the problems of rationing capital, risk, determining the aggregate cost of capital, and selection of tentative "cut-off" points. Financial terms, forms, and institutions are well defined, but the excitement and variable aspects of problems are frequently missing in the discussion, and an illusion of mechanical simplicity is sometimes created.

Topics are discussed in a systematic manner following the same format in each chapter, and few students should have difficulty understanding the material presented. The descriptive chapters provide a good reference source, although explanatory and reference footnotes are lacking. The absence of tables and charts summarizing empirical information and company experiences also

simplifies the reading job. A vast array of problems and short "cassettes" are included for student assignments. Negative style features include a surprising number of minor errors and a tendency to pulverize simple ideas. In the discussion of the use of sinking funds, the reader is instructed (p. 366), "Thus, an 80 per cent plan fully executed leaves only 20 per cent of the debt exposed to risk at maturity, while a 50 per cent plan leaves 50 per cent exposed." The author attempts to build concepts by covering the same topics in several different chapters; however, the level of discussion remains the same so the result is often simply repetition. There are many sections where identical ideas, even entire paragraphs, are repeated (for example, see pages 356-58).

Criticisms of style are insignificant relative to consideration of subject coverage. Professor Brandt has attempted to prune away the emphasis on the financing and crisis epics of many finance texts following the lead of Howard and Upton, as later expanded by Johnson and Weston. No attempt was made to create a new format similar to the efforts of Beranek or Lindsay and Sametz. His approach highlights the dilemma of finance courses in today's curriculum. From one side, the managerial accountants are pushing into the liquidity and solvency topics of finance, and from the other, the managerial economists continue to concentrate on problems affecting profits and the allocation of capital. Finance professors may ignore these contributions and continue to emphasize the familiar tools of financial analysis. At schools where accounting departments have moved toward a managerial approach, this duplication will lead to inefficient use of the early sessions of finance courses. The opposite extreme is to drop all attempts to be analytical and concentrate on descriptive reviews of various sources of funds. A suitable compromise would be to create an advanced course utilizing the analytical skills and knowledge acquired in basic accounting and economics courses to examine problems of financing, allocating funds among alternatives, capital structures, valuation, liquidity, and other financial topics. The beginning course in finance need not use a "basic" or "elementary" approach if the student first studies economics and accounting. The internal approach advocated in this book may be justified if a different curriculum is adopted. Therefore, while complimenting the author on his thoroughness and organization in the informative coverage of the topics selected, this reviewer does not believe this text solves the basic problem of deciding what the subject content of a finance course should be and what level of sophistication and breadth should be sought, relative to the amount of details and definitions of basic topics that are also analyzed in related academic studies.

Transportation Economics. A Conference of the Universities-National Bureau Committee for Economic Research. (Special Conference 17.) New York: Columbia University Press for National Bureau of Economic Research, 1965. Pp. xviii, 464. \$10.00.

The sixteen papers that make up this volume in the National Bureau's conference series provide a rather broad and representative sample of the wares currently being vended under the label of transportation economics. They range in the problems attacked from the very old to the very new, in research technique from legal case-dredging to subtle statistical methods, and in scholarly weight from routine occasional pieces to important original research. The following comments deal selectively with some of the more interesting themes and individual contributions.

Several writers are concerned with aspects of the interrelated problems of pricing and intermodal allocation in the carriage of freight. The essays by J. R. Nelson and by R. A. Nelson and W. R. Greiner together examine selected historical forces helping to explain the present dilemma of excess capacity, low returns, and inefficient pricing in railroad freight service. J. R. Nelson reviews some of the organizational and market factors that may explain the original creation and persistence of excess capacity. R. A. Nelson and Greiner explore the hypothesis that the preservation of value-of-servicing pricing "has been the dominant policy underlying transportation regulation in the United States for many years" (p. 373), due to a political interest in maintaining discrimination in favor of the long-distance movement of basic raw materials and agricultural products. The attempt to insure the conformance of motor truck pricing to a rate structure containing important elements of discrimination has had the effect (among others) of denying railroads the opportunity to compete on the basis of price for traffic that they can profitably carry and leaving the rates for raw materials and agricultural products unadjusted. Indeed, the paper by J. C. Nelson on "The Effects of Entry Control on Surface Transport" develops evidence on the costs of imposing regulation on truck transport for the protection of the railroad pricing structure, since he analyzes the real costs attributable to franchise restrictions on the operations of common-carrier trucking firms and not just to entry control per se. The paper by M. J. Roberts on "Transport Costs, Pricing, and Regulation" touches upon the substantive cost-based criteria for pricing that would most likely serve to straighten out these misallocations. Long-run marginal cost is an appropriate basis for the (minimum) pricing of rail service, as are the long-run marginal costs of other transport agencies (except pipelines) to their own minimum charges. In the case of agencies other than railroads, long-run marginal cost can largely be identified with short-run average cost. In railroads, however, the appropriate marginal-cost concept is a hybrid, representing incremental costs in a rationalized version of the present railway plant and not the costs that would prevail if the railways were optimally rebuilt from scratch.

Two papers by R. J. Gordon and G. Kraft are concerned with airline costs. Gordon attempts to develop a measure of the cost of managerial inefficiency in domestic commercial air transport, identifying it with positive deviations from cross-section least-squares regressions (or similar fits) of selected airline cost components upon their major economic or technical determinants. Valuable as this paper may be as an exploratory effort, its results (which impute most of the subnormality of the trunk airlines' 1960-61 profits to inefficiency) are a bit hard to interpret. Gordon's measure is not a maximum one, since it

rests on deviations from average performance, not from some technical optimum; nor, on the other hand, is it a minimum, since omitted cost-determining variables outside of managerial control may account for some of the positive deviations. Kraft's paper on advertising costs in the airline industry uses a Koyck-type distributed-lag technique to assess the revenue productivity of advertising expenditures. For reasons fully adduced by Kraft's discussants, his results must be rejected. They more likely reflect the effect of revenue on advertising expenditures than the other way around. And, as usual when this method is applied to autocorrelated time series, the apparent goodness of fit is quite deceptive.

The volume includes a paper by E. Mansfield from his excellent series on technical change, "Innovation and Technical Change in the Railroad Industry." His results, concerning the size of innovating firms and interfirm and intrafirm rates of diffusion, seem to raise one problem of interpretation. The Schumpeterian hypothesis invoked by Mansfield (p. 181) emphasizes the risk attached to innovation and the allegedly greater capacity of firms possessing positions of monopoly to incur it. The list of innovations investigated by Mansfield includes, quite naturally for a service industry, many that are in essence new types of capital goods, the developmental risks of which must have been borne largely by equipment manufacturers outside the railroad industry. Whatever the significance of Mansfield's findings about their adoption by the railroads, it may not be as a test of the Schumpeterian hypothesis. Was Schumpeter talking about who would build the better mousetrap, or about who would first beat a path to the door?

M. J. Peck and J. R. Meyer contribute a stimulating paper on "The Determination of a Fair Return on Investment for Regulated Industries," in which they compare to the present-value calculations of rates of return indicated by capital-budgeting procedures those measures of returns commonly used in regulatory proceedings. It is a bit dismaying to see so little made of the distinction between replacement cost, a theoretically sound rate base, and the reproduction-cost base in actual use, considering all the blood that has been spilled over the latter. Peck and Meyer evade the issue of the "normal" rate of return to be allowed once the rate base is established, except to note that, around the early 1960's, public utility industries were doing less well than selected manufacturing industries marked by moderate to high seller concentration. Do they feel that a fair return to the utilities should include a fair share of monopoly profits?

Finally, a group of papers deals with the interrelated issues of urban economics and highway passenger transport. R. W. Harbeson's review of the problem of allocating highway costs to different classes of users fails, as discussant P. O. Steiner points out, to distinguish adequately between the "equity problem" of allocating costs among users after the event and the "efficiency problem" of levying charges equal to the associated incremental costs as a condition for use. W. Vickrey provides a spirited advocacy of marginal-cost pricing, and T. Kuhn an imprecise discussion of "The Economics of Transportation Planning in Urban Areas" which mixes comments on the appropriate form of decision criteria with complaints about abuses in their actual em-

ployment. J. F. Kain develops some novel material on the trade-off between residential-space costs and travel costs for urban commuters and on the impact of racial discrimination on housing costs and locational patterns. Finally, K. T. Healy pleads for placing urban transport problems in a larger decision-making context that would encompass the possibility of discouraging the further growth of already large urban agglomerations. He could make his case even stronger by arguing that economic units adding themselves onto large metropolitan areas probably pay charges (taxes and user payments for public services) that fall well below the associated long-run marginal social costs, but as long as red blood flows in chamber-of-commerce veins he is likely to win few influential converts to his cause.

RICHARD E. CAVES

Harvard University

The Urban Transportation Problem. By J. R. MEYER, J. F. KAIN, AND M. WOHL. Cambridge: Harvard University Press, 1965. Pp. xix, 427. \$11.95.

This RAND Corporation Research Study deserves the serious attention of every student of the urban scene. The implementation of the study is impeccable: "The ultimate goal is to improve urban living, not to eliminate congestion, or maintain investments in real estate or transportation facilities as such. Urban transportation investments use resources that alternatively could be used for educational, health, recreational or other purposes." In the best tradition of descriptive (as opposed to prescriptive) economics, the authors largely succeed in their attempt to define the urban transportation problem and to explore the validity of many of the contemporary clichés about our urban transportation condition.

Part I is a well-written nontechnical discussion of trends in urban population, employment, residential patterns, trip demands, transit service, and so forth. Since the absence of adequate data precluded an econometric investigation, this section may not completely satisfy the reader accustomed to thinking in terms of income and cross price elasticities of demand. However, the authors' informed and plausible interpretation of available data does provide a clear—and not infrequently surprising—insight into the changing character of spatial activities in urban areas. The authors display this same talent for synthesizing theory and fact throughout the book.

Part II on comparative costs is the heart of the study. The authors carefully build detailed cost models for rail, bus, and automobile systems that provide the three basic urban transportation functions: residential collection and distribution, line-haul, and downtown distribution. Several dimensions of the one-way trip are standardized in order that the estimated dollar costs of the trip on alternative modes can be compared with one another. The authors specify identical speed, frequency of service, population density, convenience and comfort for each mode and proceed to estimate the dollar trip cost on each mode at various passenger-volume levels and various trip lengths. Obviously, congestion problems are assumed away at this stage of the analysis. The cost

estimates that result are too numerous to summarize in detail here since transfers, surface and underground construction, and combinations of modes are also considered as alternatives. But several conclusions are worth specific note. the freeway flier bus has the lowest trip cost of all modes, lower than rail for even high population densities. The frequently proposed park-and-ride rail system is usually the highest-cost means of providing trips. Equally interesting is the conclusion that the private automobile with an occupancy rate of 1.6 persons has a lower trip cost than either bus or rail for passenger volumes of less than 10,000 persons per hour per corridor (the case of most U.S. cities).

Part III, "Solutions and Public Policy," is both a summarization and a discussion of what contributions can and cannot be realistically expected from our technology and our political institutions. In brief, the authors advise rationing expressway space during peak hours by taxes, direct access controls, and by a priority system for express buses. They are not optimistic about the prospects for a technological breakthrough that will dramatically solve the urban transportation problem. They find improvements in existing technology more promising for the future and in this context suggest the following modifications for bus systems: more express buses, centralized fare collection, the addition of a third door with double side loading and unloading, and diagonal, multifislot, high-speed, high-volume bus terminals.

The authors are understandably reluctant to commit themselves to a general policy recommendation for urban transportation. The conclusions they do reach might be paraphrased as follows: since we know so little about the demand function for urban travel and since the capital costs of rail systems are considerable, the economic approach in most U.S. cities would be to experiment with express buses, priority express buses, and congestion-control systems on existing freeways before plunging into the construction of expensive, long-lived rail facilities. Unfortunately this approach probably lacks sufficient glamour to satisfy the political and propertied urban establishment that already seems bent on the construction of capital intensive, federally financed rail systems.

In a sense this is an untimely book; it appears too late to have a beneficial effect on those responsible for drafting the federal legislation that will shape urban development for generations to come. On the other hand, the book appears too soon to include a discussion of the detail and impact of the Urban Mass Transportation Act of 1964. The usefulness of the authors' cost estimates must surely be evaluated in the light of the provisions of that act. Although their estimates are methodologically unassailable in the context of the national allocation problem, those costs are now not relevant at the urban level where the transportation-investment decisions are made. Under the provisions of the act the federal government is prepared to pay up to two-thirds of the capital costs of a mass rapid transit system for a qualifying area. Since the capital or fixed-cost component of a rail system is much higher than that of an express bus system, the effective community costs of a new rail facility are now considerably lower. The practical urban politician realizes this, of

course, and will revise the cost equations of this study accordingly in order to find *his* cost of urban transportation.

M. BRUCE JOHNSON

University of Washington

Economics of Private Truck Transportation. By WALTER Y. OI AND ARTHUR P. HURTER, JR., WITH ERROL GLUSTOFF, SEIKO HIGA, AND DAVID R. MILLER. Dubuque: Wm. C. Brown Co., 1965. Pp. xvii, 365. \$9.00.

The role of private, as contrasted with common carrier, truck transport in the United States has long been one of the least understood aspects of transportation economics. This fine volume supplies much of the missing information. In the process, a major contribution is also made to the emerging field of transportation logistics (e.g. Chapter 8: "An Empirical Analysis of the Private Carriage Option"). Furthermore, the book incorporates (Chapter 5) the best analysis of the behavior of truck costs, both private and common carrier, yet available. Finally, a highly suggestive and original statistical analysis is presented of "The Value of Service Component in Rail Freight Revenues" (Chapter 7).

The major conclusion, though, will be as unsurprising to many transportation economists as it will be irritating to some of the more hidebound elements in the common carrier industry. Specifically, on the assumption that certain income and income redistribution effects are not dominant considerations, Walter Oi and Arthur Hurter conclude that private carriers are socially desirable on the grounds that they achieve at least some improvement in the allocation of transportation resources. Accordingly, they recommend a reduction in transportation regulation in order to evoke a more workably competitive environment in highway transport. In particular, they favor removal of minimum rate regulation as it is now applied to common carriage (by all modes). With such a change, they envisage that common carriers could compete more effectively with private trucking for certain sectors of the market, mainly short-haul traffic, where present common carrier rates seem most notoriously out of line with costs and therefore provide a considerable incentive for private carriage.

This conclusion derives from their detailed analysis of the incidence of private motor transport. Specifically, they argue, quite cogently, that private motor transport can be broadly viewed as a form of vertical integration that will be practiced by firms whenever profitable. They predict and provide evidence that this profitability is a function of several variables such as firm size, industrial affiliation, the frequency of short-haul shipments, the importance of freight expenses in terms of total expenses of the firm, the prevalence of intrafirm shipments and the extent to which the shipper (as contrasted with the consignee) bears the freight cost. On an empirical basis, the distance profile of shipments proves, somewhat unexpectedly, the most important single factor while the size of firm is less important than expected. Though medium-size firms use more private carriage than small firms, very large firms tend to use relatively little private transport. This phenomenon, incidentally, might be explained, though the authors do not investigate the point, by the greater bar-

gaining power of the very large shippers; this could enable them to extract rate concessions from common carriers much more readily than their small or medium-size competitors. Whatever the explanation, the usual defense of public policies to protect common carriers, based on the grounds that common carriers are particularly needed by smaller businesses, is at least mitigated.

Another important factor determining the substitution of private for common carriers, introduced somewhat *ad hoc* by the authors, relates to temporal variations in transport demands. They identify what they call a "base load" phenomenon. Many shippers seemingly find it advantageous to develop sufficient private capacity to meet their base or temporally steady transport requirements and rely upon for-hire carriers to take care of spillover demands which occur seasonally or intermittently. The same argument could have been extended to infer that shippers who generate temporally steady or constant demands for transportation will also have incentives to enter into private truck transport as long as pricing schemes used by common carriers do not reflect the cost effects of demand variations.

Inflexibility in the common carrier rate structure also seems to be the root cause of much of the private motor transport of short-haul traffic. Common carrier disadvantages in short-haul traffic can be substantially attributed to an inability to tailor equipment to the special needs of short-haul traffic, mainly because the common carrier has no guarantee that he will have the traffic over a sufficiently long period to amortize properly any specialized equipment investment. The private carriers, of course, implicitly possess this guarantee. In short, a major advantage of the private truck on short hauls, or any traffic requiring special equipment, is a traffic guarantee.

This, however, suggests a policy alternative to minimum rate deregulation, namely institution of so-called contract or agreed charges. Basically, these are long-term contracts entered into between the shipper and the common carrier in which the carrier agrees to a lower rate in exchange for the shipper's guarantee that a certain percentage or absolute level of traffic will be given to the carrier over a specified time period. This arrangement would enhance the competitive position of the common carrier both on short hauls and in stable demand situations, which, as noted previously, seem to account for a very high percentage of total private transport. Contract charges, incidentally, are in effect in many parts of the world today. Following Oi and Hurter's suggestion that some form of regulation will have to be continued even with elimination of minimum rate regulation, contract rates might be more acceptable if subject to regulatory review and cost justification.

JOHN R. MEYER

Harvard University

Government and the Railways in Nineteenth-Century Britain. By HENRY PARRIS. Toronto: University of Toronto Press; London: Routledge & Kegan Paul, 1965. Pp. xii, 243. \$5.75; 35s.

In many respects the economic organization of the British railways in the nineteenth century was the envy of American railroad men. Britain restricted entry to the extent of requiring an act of Parliament for construction of a line.

The country was highly developed, so that railways were typically built to serve existing population, rather than speculatively in unpopulated areas. The Railway Clearing House was a more effective force for cartelization than any of the U. S. rate associations, and the courts exempted railways from the usual Anglo-American prohibition of collusive pricing. Finally, Parliament, from a notable speech by James Morrison in 1836, was dominated by the idea that collusion among railways was inevitable. Accordingly, Britain had no counterpart of the long American effort to organize the industry competitively. Parliament from 1840 provided for public intervention in the industry through a succession of regulatory bodies. The traditional British literature on this experience is as uncritical and unrewarding as our pre-1940 literature on the ICC, and there is little question that a new study of British railway regulation in the nineteenth century is needed.

Unfortunately, it would be difficult to argue that this volume does the job. The author devotes himself in his early chapters mainly to a detailed history of public administration in the Board of Trade Railway Department and its successor organizations. He has unearthed a great deal of information on internal operation of the regulatory bodies from manuscript sources, but he has written a text such that the information is essentially its own end. The author's choice of quotations and, especially, his use of italics lead me to suspect he had some argument in mind, but I am unable to identify it. Parris' principal interest is in accident investigation and cases concerning installation of safety devices. The chapter on relations of the Railway Board with the companies is almost entirely devoted to safety problems.

Worse, Parris' treatment is most intensive on the period 1840-67, whereas the regulation was made more comprehensive by the establishment of the Railway Commission in 1873. Thereafter, rate regulation was carried on systematically in a fashion which was in certain respects a model for the ICC. One wonders, naturally, whether it was an effort at artificial depression of rates or a facilitation of the industry's cartelization, but Parris provides no answer. By analogy to the U.S. experience and a priori considerations, one presumes the latter. When a legislature establishes a body to regulate an industry, there really isn't much to do but cartelize it.

Finally, Parris is presented with a problem in intellectual history: why in a period of widespread philosophical commitment to *laissez faire* was there such early recourse to public intervention in railways? He addresses himself to this question for about two and a half pages at the outset of a chapter entitled "Railways in the Theory of Government," but his treatment is limited to a few statements of the views of major economists on the proper scope of public intervention in price determination and resource allocation. He then wanders off into a discussion of contemporary interventions: the Factory Acts, the Poor Laws, factory inspection, and the like. He attempts no serious enquiry into the views of the later classical economists or Ricardian members of Parliament on the technological characteristics of the railways which made them a special case.

Publication of this book may possibly be justified by the antiquarian information it presents on public administration, notably in connection with safety

regulation. The readers of this journal are presumably interested in it as a piece of economic history. So viewed, it is thoroughly inadequate. Pratt and Cleveland-Stevens did a better job of writing on the subject in the World War I era and, to judge by the wealth of Parris' citation of sources in the Public Record Office, with a smaller expenditure of resources in the process.

GEORGE W. HILTON

University of California, Los Angeles

Air Transport Policy and National Security—A Political, Economic, and Military Analysis. By FREDERICK C. THAYER, JR. Chapel Hill: University of North Carolina Press, 1965. Pp. xxiii, 352. \$8.00.

Despite the subtitle, the "analysis" offered in this volume is very largely confined to the two concluding chapters, which deal with present policy problems connected with military airlift and international air transport regulation, respectively. The other nine chapters, making up over two-thirds of the text, might better be described as "annals."

According to the dust jacket, the author holds the rank of lieutenant colonel in the Air Force, in which he has served since 1945; moreover, "he has spent eleven of those years in operational and staff assignments involving airlift or air transport." It is therefore not surprising that the subject of what appears to be his most closely reasoned chapter should be military airlift—specifically, the relevant policy decisions of the Kennedy administration, which Colonel Thayer finds "contradictory to each other" (p. 263), and his own suggestions for their correction. However, even the military nonexpert cannot but be aware that this analysis, though seemingly cogent, would need supplementation from non-Air Force sources in order to provide sufficient basis for evaluating the proffered recommendations. Those whose primary interest is in civil air policy will find here little help in answering the principal question which must concern them in connection with military airlift: namely, whether there is any military airlift requirement which can be met most efficiently by some modification of governmental policy towards commercial air transportation—e.g., by some form of subsidy.

In the absence of a clear answer to this question, attempts to relate commercial air policy to military airlift needs must tend to be confused and indecisive. This conclusion is borne out by Thayer's detailed narration of major and minor events connected with the pre-Kennedy airlift controversy, which accounts for some three-fifths of the historical section of the book. Political and military historians may find this narration, as well as Thayer's treatment of World War II airlift, to be of assistance in piecing together a fairly complex story.

The remainder of the historical section, which takes up national and international airline policy, goes over ground that has been more thoroughly and objectively covered in other works—for example, in Richard E. Caves's *Air Transport and its Regulators* (Harvard, 1962) and the sources cited therein.

In his analysis of international air transport policy, Thayer is handicapped by unfamiliarity with the facts and lack of sophistication in dealing with economic theory. He believes, for example, that the rate-making machinery of the

International Air Transport Association (IATA) constitutes "*de facto* regulation" (p. 68); that the United States has refused to "consider the possibility that the IATA apparatus may be the best middle ground available" (p. 83); and that this country's promotion of export sales of aircraft to foreign airlines is resulting in higher postage rates through increases in subsidization of our carriers by means of mail payments (p. 282). In fact, according to the calculations of the Civil Aeronautics Board, mail payments to U.S.-flag international air carriers have contained no element of subsidy since the late 1950's; furthermore, past subsidies had little or no effect on postage rates. The IATA and its rate-making procedures exemplify the general proposition that where enterprises are operated by governments—as most of the foreign air carriers are—the regulatory function is absent, neglected, or weak. In the Statement on International Air Transport Policy approved by the President in April, 1963, IATA rate-making is characterized as follows: "This multilateral mechanism, though it has some drawbacks, seems to be the most practical one we can achieve, and it should be maintained."

Thayer's contact with economic theory has persuaded him that the existence of oligopoly, with its departure from pure competitive pricing and its presumed promotion of "wasteful" competition in selling, justifies the institution of "government-industry partnership" covering both domestic and international air transportation (p. 297). Domestically, the "general rule for restructuring the industry would have to be that only one carrier operates across any particular route except where it is utterly impossible to avoid direct competition" (p. 296), and the industry should undergo a drastic rationalization and paring down of profits. International service by U.S.-flag airlines should be carried on by three companies, each serving one region of the world (pp. 304-6). Economists must shoulder some part of the blame for this sort of immediate translation of partial and tentative economic analyses into policy recommendations, not only with respect to air transportation, but in the large number of other fields exhibiting similar market characteristics.

Thayer's recommendations on international air policy are indeed partly defended by an appeal to special considerations: first, what seems to this reviewer a thoroughly obscure analogy with a doctrine of Admiral Mahan regarding sea power ("National power, he argued, depends upon military and economic dimensions of naval strength—the Navy and the Merchant Marine" (p. 300)); and, second, the need for overseas air bases in time of war. It should be obvious, however, that peacetime use by U.S. airlines is neither necessary nor sufficient for the wartime security or availability of such bases.

A recurring note in Thayer's work is the assertion that the U.S. government harbors an unreasoning hostility towards U.S. airlines. In connection with route negotiations, he believes, the interests of these carriers are inadequately represented; "the government still holds that it cannot assist U.S. airlines because they are private enterprises, but it must hurt them in the national interest" (p. 79). A glance at the international route map should suffice to dispel any impression of general ineffectiveness on the part of U.S. negotiators. There seems nevertheless to be one area—not mentioned by the author—where officials have fallen short of what might be reasonably expected in pur-

suit not only of equal opportunity for our carriers, but of maximum economy and efficiency in international air transportation. The power to suspend service by foreign air carriers, which is within this country's prerogative under the Bermuda-type bilaterals, was not available for use in the celebrated North Atlantic fare controversy in the spring of 1963 and, as far as this writer knows, is unavailable still, apparently because of official failure to provide the necessary legal machinery. Speedy repair of this oversight would help to silence allegations such as those made by Thayer.

Edinyi energeticheskii balans narodnogo khoziaistva (problemy optimizatsii). (Over-all Balance of Energy in the National Economy—Problems of Optimization.) By S. D. FEL'D. Moscow: Ekonomika, 1964. Pp. 311, Appendices.

Atomnaya energiya v narodnom khoziaistve (Ekonomika i primeneniia). (Atomic Energy in the National Economy—Economics and Utilization.) By W. I. POSTNIKOV AND I. M. RAZUMOV. Moscow: Ekonomika, 1964. Pp. 175.

Energia jądrowa w Polsce w latach 1955-1960. (Nuclear Energy in Poland, 1955-1960.) Edited by JOZEF HURWIC. Warsaw: Wydawnictwo Naukowe, 1963. Pp. 394. English Summary.

During the past few years, energy problems have attracted a great deal of academic attention in the Soviet Union. This has been reflected not only in a growing number of publications dealing with one or the other aspect of their own energy economy,¹ but also in a pronounced interest in similar inquiries elsewhere, especially in the United States.² Nevertheless, up to now, the Soviet energy studies lagged behind such undertakings in the West, notably in methodological refinement and analyses of the fundamental intersector energy flows in the national economy.

S. D. Fel'd attempts to fill in the gap in both directions. On the one hand, he offers his own methodology for constructing a uniform over-all energy balance sheet for the USSR and, on the other, he presents the very first Soviet intersector energy flows. These are restricted to four selected years (1910, 1928-29, 1958, and 1965—as planned) with greatly unequal periods and many socioeconomic upheavals in between, so that they do not permit a definite conclusion about the effects of Soviet energy balances on economic de-

¹ See, e.g., *Toplivno-energeticheskii balans SSSR* (The USSR Fuel Balance), by A. A. Riznik and C. E. Litvak, Moscow 1965; *Ekonomika Energetiky* (Economics of Energy), by L. A. Melentev and E. O. Shteingauz, Moscow 1963; *Toplivnaya promyshlennost SSSR i ekonomicheskaya effektivnost kapitalovlozhenii v ee razvitie* (The USSR Fuel Industries and Economic Effects of Capital Investment in Their Development), by G. D. Bakulev, Moscow 1961; *Toplivnyi balans SSSR* (The USSR Fuel Balance), by D. I. Maslakov, Moscow 1960.

² They recently translated *Energy in the American Economy, 1850-1975*, by Sam H. Schurr, Bruce Netschert, et al., Baltimore: Johns Hopkins Press, 1960.

velopment. In spite of this, however, these flows offer useful information on changing energy patterns in the USSR.

The book is divided into five parts, the first of which is devoted to definitional and theoretical issues generally encountered in constructing energy balance sheets. The subsequent parts are more oriented toward specific Soviet energy problems. The second and third chapters deal with efficiency in Soviet production and utilization of energy, respectively, while in the fourth chapter, Fel'd examines the complex link between economic growth and the structure of the energy economy. This is, in effect, a pivotal issue in Fel'd's work because, as he points out, the present Soviet economic plans, in regard to their energy base, are predicated on rather simple and mechanistic formulas of a technically attainable maximum output of the respective energy resource. Little, if any, attention is paid to considerations of an optimal solution, mutual substitution, and relative costs of individual fuels and hydroenergy. As may be expected, it is in the concluding chapter that the author presents his own model, based on linear programming, which should permit construction of more economics-oriented energy plans within the framework of a Marxian state.

Conceptually the author's approach rests on a cost accounting in real terms expressed in kwh (or kcal) of useful energy as needed in productive as well as nonproductive sectors of the Soviet economy. His main analytical tools include a complex concept of the "useful energy cost," that is, a sum of all useful energy inputs needed per unit of specific output. As a second step, the concept is extended to cover output of the entire industry. To that is related the industry demand for a certain quantity of potential energy in all raw inputs while the link between the two is provided by a coefficient which, generally speaking, corresponds to "thermal efficiency" as defined by Schurr.⁸ The cost of producing energy is calculated in man/days (years) per unit of potential energy. An optimization criterion is the minimum total cost of all the useful energy which is determined in the given national plan as needed by the economy.

There are a number of inconsistencies in Fel'd's concept of an integral "energy cost" in the entire economy. To name only one, he omits fodder for animals from his computations although he does include therein the contribution of animal power. Also, the difficulties in computing and expressing the intra- and interindustry input-output flows in corresponding real terms of direct and indirect "energy cost" justifiably raise a question about the model's practicality. Nevertheless, in many respects, the study by Fel'd makes interesting reading.

Fel'd pays only perfunctory attention to the economic impact of atomic energy. One would expect that this question will be more adequately treated in the book of W. I. Postnikov and I. M. Razumov, whose title suggests that it is a specialized study. It is not, however; the authors merely repeat generally known assumptions about nuclear economics and in the rest discuss the uses of radioisotopes. Similarly, the Polish book edited by Jozef Hurwic is mainly

⁸ Schurr, *ibid.*, pp. 171-72.

oriented toward a review of institutional developments rather than to economics of nuclear energy application in Poland.

Resources for the Future

**Land Economics; Agricultural Economics;
Economic Geography; Housing**

Planning in Chinese Agriculture—Socialisation and the Private Sector, 1956-1962. By KENNETH R. WALKER. Chicago: Aldine Publishing Co., 1965. Pp. xviii, 109. \$5.00.

The subtitle "Socialisation and the Private Sector, 1956-1962" more accurately describes the contents of this compact and well-documented book. This is one of the first Western books to explore a Communist Chinese enigma: how to increase real per capita agricultural output above the pre-Communist level within the Marx-Lenin-Mao framework of communal ownership of all productive resources.

Professor Walker records and analyzes the Communists' plans and programs in three parts. In Part I, he traces the Communists' step-by-step socialization of agriculture with land reform ending in 1952, peasants' mutual aid teams in 1954, agricultural producers' cooperatives in 1955, collectives in 1956, and communes in 1958 (p. 14). In Part II, the author analyzes the economic significance of the private plots to the individual peasants and to the Government. In Part III, about half the book, he chronicles the Communists' vacillating policy toward private plots from harassment in 1956-57, to abolition in 1958, and to restoration in 1961. Private plots, accounting for 5 to 7 per cent of China's total cultivated land, continued to prosper in 1965 (see "China's Agriculture" in *Foreign Agriculture*, FAS, USDA, Nov. 22, 1965, p. 2).

The quantities of food, fiber, and fertilizers produced on these private plots are a matter of conjecture. The author estimates that the modal amounts of food available to peasants from private plots in 1956, based on samples from many areas, were 72 grams of pork, 56 grams of vegetables, and 284 calories per capita per day (p. 30). Average amounts were substantially higher especially of vegetables. Grain from the collective sector was estimated to provide 1,792 calories per day. Roughly 14 per cent of the peasants' total calories came from private plots which raised their caloric intake above the subsistence level. Workers fared better because about 40 per cent of the population was either under 16 years of age or over 60.

The percentage of peasants' real disposable income from private plots varied from 13.7 per cent in Northwest China (1956) to 33.6 per cent in South China (1957) (p. 34). Total net disposable income per head was higher in the wheat-North than in the rice-South. These data suggest greater productivity on the private plots than on the collectives in the South where labor requirements per hectare are high. In the agriculturally diversified Fukien province, net income from private plots, as a percentage of total income, ran as high as 67.3 per cent (p. 39).

The more profitable private sector drained labor, managerial skills, and animal fertilizer from the collectives. In an effort to contain peasant capitalism, private plots were restricted to 5 per cent of a collective's land as a national average (p. 43). To further control private incentives the farmers' free market was closed in August 1957 (p. 73). Finally, private plots were abolished with the advent of the communes in 1958 (p. 75). Their abolition eliminated an embarrassing contradiction but Communist planners believed that private plots were no longer needed. Food was in ample supply and the efficiency of communal messhalls, producing their own poultry and hogs and serving free food, was to more than offset the loss of food from private plots (p. 76). The freed labor was expected to increase the output of the agricultural collectives which provided the bulk of the food calories and the savings for industrial investments.

The Great Leap Forward, statistically successful, lowered real agricultural output drastically. The shift of skilled farm labor to mines and factories, and natural disasters, decreased the food supply while the demand for food increased due to the free-food policies of messhalls and the swelling of the urban population. The huge Chinese population was reduced to a near-starvation level in 1960-61 (p. 83).

If there is a central character in this excellent treatise it is the pig. But unlike his dictatorial role in George Orwell's allegorical novel *Animal Farm*, Professor Walker's pig is more of the hero-type. The pig plays a vital role in not only supplying the population with essential animal proteins but also in producing a scarce and valuable resource: manure. In 1955 pig manure was produced at 24 kilograms per hectare of arable land as contrasted to only 14 kilograms of chemical fertilizer (p. 56). The pig population declined by more than 17 million during the early years of collectivization which resulted in less pork for urban markets and less pig manure that the collectives sorely needed.

Apparently, pigs do not prosper under collectivized management. Half of the collectivized young pigs died in 1960 because of diseases (pp. 67 and 94). The Communist Party, anticipating disaster, returned pig rearing, accompanied by appropriate incentives, to private hands in 1959 (p. 81). According to *Foreign Agriculture*, cited above, about 80 per cent of the hogs and 95 per cent of all poultry are presently raised on private plots in Communist China.

Gerald Winfield in *China: The Land and the People* (New York: William Sloane Associates, 1948) makes much of China's traditional "organic union of man with the land" (p. 46). The Chinese Communists set out to alter this symbiotic relationship. Yet, we are mindful that Russia after nearly 50 years of trial and error is still largely dependent on the private sector for her supplementary foods, and is a large importer of grains. China, too, continues to accommodate contradictions by tolerating private plots, supposedly as long as peasants do not exploit each other, and by importing wheat while exporting rice obtained by the Government's exploitation of agriculture and the collectivized peasants.

Though Professor Walker's numerous calculations may be suspect due to the paucity and credibility of available statistics, yet he clearly depicts the tribulations encountered by the planners, and the peasants, in Communist

China's attempt to industrialize rapidly. Many of their grandiose schemes have been shelved. Messhalls have been abolished and small production teams have been delegated the decision-making, income-sharing responsibilities subject, of course, to Party directives. After 15 years of experimentation it appears that the more Communist China's agriculture changes, the more it returns to earlier forms.

Labor Economics

Forced Labour and Economic Development—An Enquiry into the Experience of Soviet Industrialization. By. S. SWIANIEWICZ. Issued under the auspices of the Royal Institute of International Affairs. London: Oxford University Press, 1965. Pp. xi, 321. \$7.20.

The author of this study of forced labor in the Soviet Union sees a certain dilemma confronting underdeveloped countries with agricultural overpopulation; the choice is to grow at a "snail's pace" or to face the harsh problems that a program of forced economic growth entails. The success of forced economic growth in the USSR makes it an attractive model for many countries, but its attractiveness is marred by the use of forced labor. The objective of this study is to examine the role of forced labor in Soviet development in the hope that ways may be devised for other countries to pursue development programs without having to resort to that technique.

The principal function of forced labor in the prewar period (in which the study concentrates) was to carry out the redistribution of labor required by the development plan. During the early 'thirties the task was to move the surplus agricultural labor off the farms into industry and construction. Because of the "wage-goods gap," normal economic incentives would not have accomplished the shift. The policy of "dekulakization" directly removed several million peasants to forced-labor camps and to forced settlements, and indirectly contributed to further mobility by encouraging others to leave their villages and by strengthening the official labor-recruitment organs. The author raises, but does not directly answer, the question of whether the policy was a "historical necessity," though his data suggest that on economic grounds the answer would be negative. The "wage-goods gap," for example, which motivated the policy, was in fact aggravated by the losses sustained in agriculture and by the opportunity cost of forced labor.

In the late 'thirties, the purpose of forced labor changed from the elimination of agricultural unemployment to the distribution of scarce labor "in accordance with governmental priorities," particularly to the investment ventures of the NKVD. The author stresses the importance of these projects, but in his calculation of the cost of forced-labor operations, he finds that the wage savings from the use of forced rather than free labor is almost offset by the high cost of the surveillance activities of the NKVD. The calculation does not take into account the lower productivity of forced labor, which would presumably tip the balance well toward free labor. He finds in summary that "it is

gard. (2) A model of organizational conflict is conditional on a model of an organization. A model of an organization should require that a position be taken on the group-decision problem. Walton and McKersie are not very specific about such matters. (3) Three-party conflicts often give birth to coalition formation, destruction, and the essentially intransitive behavior that disrupts many labor (and other) negotiations. These considerations, which would seem to be of crucial importance in the steel situation, for example, receive little more than passing attention from Walton and McKersie.

But, then, the offer of such additional teeth might serve only to emphasize a mandibular deficiency of the discipline. The enamel offered by Walton and McKersie is of good quality, and fills some unattractive gaps.

LAWRENCE E. FOURAKER

Harvard University

The Economics of Vocational Rehabilitation. By RONALD W. CONLEY. Baltimore: Johns Hopkins Press, 1965. Pp. xii, 177. \$6.00.

This book is a worthwhile though somewhat tedious addition to the growing literature on human capital. Ronald Conley's topic—the retraining of disabled workers—should interest those who are concerned either with the economics of medical care or of education.

Over three million people are currently excluded from the labor force because of physical or mental disorders, a loss of about \$10 billion annually in national income. Numerous others can work only part-time or at low-productivity jobs. Assistance to the disabled is provided by many private charities and government agencies. Conley concentrates on the federal-state program of vocational rehabilitation, which currently restores more than 100,000 people yearly to gainful employment. His main contribution is an analysis of the costs and benefits of this program to the individuals directly involved and to society as a whole.

Ideally, in calculating the social value of rehabilitation one should include the resulting increase in national income, housekeeping, and other self-sufficient services, and the decrease in medical, custodial, and nursing care required by the disabled. These should be summed over the entire lifetime of the rehabilitee and discounted to the present. An imputation should be made for nonmaterial gains. These benefits should then be compared with the social costs of rehabilitation, including counseling services, training, special medical attention, and foregone earnings.

In practice, as is often the case, it is very difficult to carry through this ideal calculation. As a rough approximation of social benefits, Conley uses increased earnings. He realizes that this covers only the first component mentioned above—increased output—and is an imperfect measure even of that. Annual program expenditures are used as a rough approximation of social costs, although this too is an understatement. Between 1959 and 1963, the present value of future increased earnings for each year's rehabilitees ranged between \$.7 and \$2 billion, the exact amount depending on year, estimation method, and discount rate. Dividing by annual program costs, which grew from

\$75 million to \$117 million during this period, Conley derives a return of \$10-\$17 for every dollar invested.

Unlike some comparable studies, Conley recognizes that these average returns are not necessarily indicative of marginal returns, and it is the latter concept which is relevant to the question of optimum expenditures. According to Conley's admittedly crude estimates, during the past decade marginal increased earnings for the first year after rehabilitation have exceeded marginal program costs. But marginals seem even more troublesome to measure than averages, so one is relieved when Conley points out that, in theory, at least, an a priori determination of the optimum expenditure level is not needed. Given an efficient referral system and rehabilitation counselors qualified to weed out unsuitable cases—two prerequisites which are currently lacking—we can simply allow the system to grow to its optimum size on the basis of decentralized decision-making.

Conley develops another interesting policy conclusion, concerning the allocation of rehabilitation funds among different subgroups within the population. As one might expect, earnings after rehabilitation tend to be higher for those who are younger, more educated, white, and suffering from physical disability rather than mental illness or retardation. However, these characteristics seem much less reliable in predicting the *increase* in earnings due to rehabilitation, and even less in predicting increased earnings per dollar of rehabilitation costs. Apparently, these groups were doing better than the other disabled even before rehabilitation; also, their rehabilitation costs tend to be relatively high. Therefore, and somewhat surprisingly, it may be just as rational for society to help the low-productivity disabled as the high-productivity disabled.

In reading this book, one is inevitably led to wonder about the rationale for government intervention. If the benefits of rehabilitation so greatly exceed the costs, why are the disabled themselves unwilling or unable to bear the temporary expense? One might interpret the entire rehabilitation program as a compulsory insurance scheme which society has undertaken to fill a void left by the private sector. But what, if any, is the relevance of the more traditional theories of public finance? Conley provides information and ideas bearing on this issue, although he does not discuss it directly.

Certainly, rehabilitation is not a public good; it is parcelled out to individuals who could, if necessary, be compelled to pay. Economies of scale may be significant, but this has not prevented private production of other goods and even of some services used within the rehabilitation program itself, in return for compensation by the government. If the private sector has not functioned adequately in providing broader rehabilitation services, is this primarily because of externalities, imperfect capital markets, or some other form of failure? This is not a mere academic question, for different answers have different policy implications. If the difficulty lies in the inability of individuals to finance investment in themselves, even when profitable, a system of government loans or government-insured loans might be preferable to our current system of direct public payments, unless income redistribution is an explicit

goal. On the other hand, subsidies are the logical remedy for externalities.

Conley does not discuss capital market imperfections, undoubtedly an important aspect of the problem. Nor does he demonstrate the existence of the usual type of externality. However, he indirectly suggests some reasons for a divergence between private and social benefits. Although average returns are high, the variability of success among individuals is also high, and if these individuals are risk-averse, investment in rehabilitation may not be rational for them although it is for society as a whole. Also, society gains from the total (before-tax) productivity of the rehabilitee, while the individual gains only from his after-tax income.

Apparently, the chief source of disparity arises from other government payments to the disabled, such as social security, public assistance, and workmen's compensation. These payments will often diminish or disappear once the individual becomes self-supporting; hence, his net increases in income stemming from rehabilitation may be virtually nil. In contrast, the elimination of these subsidies upon rehabilitation constitutes a substantial gain to the taxpayer. Thus, we are led to the rather disturbing conclusion that a major rationale for future government activity is past government activity, and that this intervention has reduced the incentive of the individual to help himself.

On the whole, Conley's is a careful and straightforward presentation. He goes to great efforts to detail the various interpretations and limitations of his data. While this should be and generally is a strength of the book, unfortunately it also becomes a weakness. Because of the organization of his material, he is forced to repeat many of these points, each time in a slightly different version. Consequently, his book suffers from a redundant and cumbersome style, which partially blurs its major arguments and obscures its potentially provocative economic implications.

ESTELLE JAMES

Stanford University

Population; Welfare Programs; Consumer Economics

The Residual Factor and Economic Growth. Paris: Organisation for Economic Co-operation and Development, 1964. Pp. 279. Paper, \$5.00.

This, another volume emanating from the OECD Study Group in the Economics of Education, contains the papers and formal comments presented at a 1963 Paris Conference devoted broadly to the subject matter denoted by the title. In fact, and not surprisingly, the almost universal concern is with education—both its contribution to past growth and its projection for future development. The principal contributions are by Denison, Svernilson, Tinbergen and Bos, and Vaizey, with observations thereon by more than a dozen discussants. There is relatively little here that is novel. Denison's attempt to measure the role of education in modern U.S. growth is well known, although here he also seeks to extend the method, unconvincingly, to cross-section international comparisons. Tinbergen and Bos report upon a variety of educational planning models rooted in the notion of a fixed manpower requirement for final output; a fuller account is to be found in another recent OECD monograph, *Econometric Mod-*

als of Education. Vaizey's interests span both worlds, and his skeptical reception of the premises of each will be familiar to readers of his earlier book. Finally, there is Svennilson's vintage capital approach to technical progress—hardly unique at this juncture—and perhaps less adequately explained here than elsewhere; indeed, since the relevance of all this to education appears only as a postscript, and then without conviction, it is not entirely clear why the material is included.

The contribution of the volume is twofold. Casual readers of the literature relating to education are permitted to savor of the principal conventional approaches to the subject as advanced by their leading expositors (the rate of return calculation favored by Schultz, Becker, *et al.*, is very closely related to Denison's method, and involves only an explicit allowance for cost). More well-informed students of the subject, on the other hand, can benefit from the direct confrontation of these different views as inspired by the conference.

The central point of contention, it soon becomes clear, is the way in which skilled labor enters the aggregate production function. Implicit in the Denison calculations, or more rightly, the American school, is a neoclassical view: smooth, continuous substitution among different types of labor of varying quality; the differential market wages associated with given educational levels then become the arbiter of the productivity of education. For Tinbergen, *i.e.*, the Continental school, the central characteristic of the production relationship is complementarity: different skills are necessary to final output, in fixed proportions, whence it follows that marginal productivities are undefined and wages determined by other forces. Each group proceeds to criticize the other for its central premise, with the English almost equally disdainful of both. Kaldor and Balogh are particularly vigorous in their simultaneous denial of marginal productivity and reluctance at anything so formal as manpower planning, in each instance without specifying constructive alternatives. Vaizey, while hardly devoid of criticism, has the redeeming virtue of directing attention to the various shortcomings of all the current approaches—the failure to differentiate quality in the educational variable, for one, and the lack of concern with the interrelationship of education with diffusion of technological change, for another—in a positive vein.

Relatively little of the discussion, unfortunately, is devoted either to empirical analysis of the divergent views or to potential improvements in the application of each set of assumptions. Sen, however, did produce data showing widely divergent ratios of secondary and university students to output, which directly calls into question the assumption of inflexibility over large ranges. Fixity within the context of a planning model can be justified, but those fixed coefficients in turn must be related to the structures of wages and extent of capital in individual countries—a variation Tinbergen largely ignores. Likewise, one might wonder at the relevance of another favorite Tinbergen device—a solution in terms of balanced paths wherein all types of educational capital retain a constant ratio to output. No historical time series exhibits such behavior, and I would have thought the problem was precisely the initial insufficient ratio of human capital to output which required rectification.

The Denison method, too, is not without its problems. The failure within

the context of a neoclassical approach to allow for substitution between formal education and other types of investment in humans—health outlays, say, or job training—as well as with physical capital is certainly notable. Individuals with greater education may earn more in part because more of physical capital and of other forms of human capital are characteristic of their selected occupations. The Denison demonstration that a 60 per cent adjustment of actual wage differentials seems to reflect correctly inherent differences in intelligence levels still leaves this further point unresolved. Similarly, since more than half the contribution of formal education derives from an increasing length of the individual school year rather than curriculum years, this adjustment is of the greatest importance. Malinvaud shows that if elementary school pupils alone benefited from the change—as Denison himself seems to suggest—the appropriate adjustment is considerably smaller than Denison's own. This is apart from the question of whether added days of attendance are on a par with completion of added years—a question subject to empirical test (but not easily) by calculating the differential income of those groups receiving fewer days of education but equivalent years.

Given the divergent major objectives of the American and Continental schools—measurement and planning—it is not surprising that different approaches to the role of education should have evolved. Yet, each also has something to bring to the other. One of the most useful grafts to the planning strain would be the rate of return emphasis so characteristic of work in this country. Even when manpower requirements are absolute, such a calculation makes sense: does it cost more, in terms of discounted output, to generate the skills requisite for additional production than the production itself is worth? The assumption is that it does not, and hence that one should simply go ahead to the extent required, but a careful analysis of the structure of wages, and hence opportunity costs, is required to justify it—something the Continental approach does nothing to encourage. Once we relax the assumption of fixity to allow for multiple activities both in final production and within the educational sectors, we naturally approach more closely to a neoclassical world, and the rate of return becomes all the more central. Planners precisely should be the ones to concern themselves with maximizing the benefits of producing more or fewer graduates of a certain type by different techniques. (And they should also pay more attention to quantification of such indirect gains as complete literacy are supposed to provide to assure that the calculus bears some semblance to reality!)

On the other side, the manpower-requirements emphasis does afford a means of translating the exact calculations of the past influence of education into a more valuable policy tool. Denison's future projections carry less force because they assume the same pattern of educational productivity differentials to prevail in the future as in the past. What the manpower forecasts permit, imperfectly to be sure, is some assessment of changing demands and hence potential changes in the future rate of return. Governments, and individuals, influenced by such expectations will presumably make better decisions than by relying upon the calculated historical rates. Whether we are currently under-

investing in college education requires some estimate of 1970 and 1980 returns, not those of 1940, 1950, and 1960.

As this little volume shows, the progress in the economics of education over the last decade has been substantial, to the point of controversy. What it also demonstrates is the considerable research potential the field still possesses.

University of California, Berkeley

Education and Economic Development. Edited by C. ARNOLD ANDERSON AND MARY JEAN BOWMAN. Chicago: Aldine Publishing Co., 1965. Pp. x, 436. \$10.75.

C. Arnold Anderson and Mary Jean Bowman have edited the papers presented to a conference on the role of education in the early stages of development held in Chicago in 1963. It was sponsored jointly by the Comparative Education Center of the University of Chicago and the Committee on Economic Growth of the Social Science Research Council.

The papers fall into four main groups. The first deals with "Human Resources" from the point of view of investment and includes a paper by A. Kahan on traditional Russian views of education as investments. These views are a surprising series of anticipations of work later undertaken at Chicago by Professor Schultz and his colleagues. A. Harberger then analyzes the relative rate of return on investments in men and in machines in India, and finds that the rate of return on a very conservative estimate is no less on men than it is on machines. This is a careful, analytical piece of work. H. Leibenstein and L. Hansen complete this section with two papers on "Shortages and Surpluses in Underdeveloped Countries" and a study of the needs for teachers in educational expansion. This last paper by Hansen is a particularly incisive and worthwhile contribution to a complex area of educational planning and represents a useful piece of analysis of a labor market having certain specialized features.

The second major section deals with "The Formation of Human Competencies" and is a survey of the way in which education has developed at home and in school and on-the-job, particularly in the United States. It is a collection of essays, including two by Mary Jean Bowman, dealing with a wide range of topics, from training on-the-job, to technical education in India at the beginning of the century. Perhaps the most important article in this section is one by Foster, "The Vocational School Fallacy in Development Planning." It is concerned with a special study of Ghana in which the author contends that the emphasis upon vocational school training in developing nations is mistaken and, in particular, he launches an impressive attack upon various ideas for the use of agricultural education as a basis for planning educational development. This article is not necessarily to be accepted as universally applicable without further investigation, but it represents a welcome piece of argument pointing in a different direction from what has come to be commonly accepted.

The last two sections of this book are concerned with "The Diffusion of

Schooling, Technologies, and Educational Opportunities" and represent an analysis of the way in which knowledge is diffused throughout the world and the way in which the labor force and the education system have developed in the course of economic development. This ends up with some studies of Czarist Russia, seventeenth- and eighteenth-century England, and the Meiji Period in Japan. C. Arnold Anderson develops an argument in his article (which is concerned with the level of literacy and schooling in some historical cases of societies on the point of takeoff) that a relatively high degree of literacy prevailed in England and New England, and that a system of elementary education "complete in itself," which was surprisingly extensive, emerged in these countries. But as development took place, education lagged. Partly, according to Anderson, this was because the urbanization of the workers led to greater social isolation and a fall in the provision of community facilities, partly because the sense of community identity atrophied, so that the pressures for all children from a village or market town to attend the local school died away, and partly because the middle classes came to provide themselves with their own schools. This is an interesting thesis that is not really confirmed by the other articles; though it is fair to say that they do not attack the same question directly. It has, of course, some relevance to the place that publicly-provided education—especially of a material kind—must play in economic development.

This is a worthwhile collection of articles which will make a useful introduction to this subject for those who are interested in the place of education in economic development.

NOTES

The Nominating Committee of the Association announces the following list of candidates for office:

President Elect:

Kenneth E. Boulding, University of Michigan

Vice-Presidents:

William J. Baumol, Princeton University
Gerhard Colm, National Planning Association
John T. Dunlop, Harvard University
Robert Triffin, Yale University

Executive Committee:

Kenneth J. Arrow, Stanford University
Richard A. Easterlin, University of Pennsylvania
Franco Modigliani, Massachusetts Institute of Technology
Joseph A. Pechman, The Brookings Institution

Ralph L. Andreano, University of Wisconsin, was named as the Association's representative to the ACLS. Albert Rees, University of Chicago, was named as a representative of the Association on the Board of Directors of the Social Science Research Council.

The membership of the Nominating Committee was: Marvin Frankel (University of Illinois); Kermit Gordon (The Brookings Institution); Bernard F. Haley (University of California, Santa Cruz), chairman; Juanita M. Kreps (Duke University); Stanley Lebergott (Wesleyan University); and David W. Slater (Queen's University).

VISITING SCIENTIST PROGRAM IN ECONOMICS

The American Economic Association has received a grant of \$5,750 from the National Science Foundation to establish a "Visiting Scientist Program in Economics." The purpose of this program, which parallels those previously established in mathematics and the physical sciences, is to stimulate improved teaching and interest in modern economics at colleges and universities whose major focus is at the undergraduate level.

The NSF grant provides financing for visits to such campuses by distinguished economists, who normally will spend a day or a day and a half on such a visit. The program for each visit is planned jointly between the visitor and the host institution; customarily it includes a talk to undergraduate major students, perhaps an informal seminar with faculty and students, discussion of current course and research interests of the host faculty, and other activities as may be desirable. While the ultimate concern is to encourage greater interest in, and better teaching of, economics at the undergraduate level, visitors' talks may be on research, current developments in economics, policy issues, or other topics that may seem appropriate to the needs of the particular institution.

This program will be under the general direction of the Association's Committee on Economic Education. Professor Phillip Saunders, department of economics, Carnegie Institute of Technology, will be administrator of the program, under the policies established by the Committee. Professor Saunders will have an informal roster of economists around the country who may be available for such visits, depending on their own schedules and the degree of common interest between them and the inviting institutions. Institutions are free to suggest visitors they would especially like to have, so long as these are within a radius of 100-200 miles of the campus, in order to minimize traveling costs. The host institution is expected to provide lodging and meals for the visitor when he is on the campus; other costs will be covered by the NSF grant.

The program is a small, experimental one for 1966-67, so it will be possible to accept only a limited number of requests during the coming year. If the program proves to be valuable, the Committee on Economic Education hopes to expand it in the following years.

Any institution which wants further information on this program, or which wishes to submit a request for a "visiting scientist" during 1966-67, is invited to write directly to Professor Saunders at Carnegie Institute of Technology, Pittsburgh, Pennsylvania 15213.

NATIONAL INSTITUTE OF SOCIAL AND BEHAVIORAL SCIENCE

The National Institute of Social and Behavioral Science, in collaboration with the Section on Social and Economic Sciences of the American Association for the Advancement of Science, will hold its regular sessions for contributed papers at the annual meeting of the AAAS in Washington, D.C., December 26-31, 1966.

Association members interested in presenting a paper at these sessions are invited to forward titles and abstracts of some 300 words not later than September 1st to Donald P. Ray, Director, National Institute of Social and Behavioral Science, 863 Benjamin Franklin Station, Washington, D.C. 20044.

Papers should be based upon the current research of the author. Subjects may relate to any aspect of national or international economics; multidisciplinary studies are also of interest. Selected materials of the sessions of the National Institute will be published in its *Symposia Studies Series*. The annual meeting of the AAAS is the largest professional meeting held, embracing all fields of science. The American Economic Association regularly holds symposia sessions at AAAS meetings as an affiliate member of the Section on Social and Economic Sciences. The contributed papers program of the National Institute is supplementary to these sessions.

AER MANUSCRIPTS

The following manuscripts, exclusive of comments and replies and in addition to those listed in the June 1965 and December 1965 issues, have been accepted for publication in subsequent issues of the *American Economic Review*:

- Robert Baldwin, "The Role of Capital-Goods Trade in the Theory of International Trade"
- J. O. Blackburn, "Progressive Taxes, Growth, and Proportional Revenue"
- J. S. Coleman, "The Possibility of a Social Welfare Function"
- E. D. Domar, "On Collective Farms and Producer Co-operatives"
- R. A. Easterlin, "Economic-Demographic Interactions and Long Swings in Economic Growth"
- H. G. Grubel and A. D. Scott, "The Role of Foreigners in the Economic Profession"
- Edwin Kuh, "The Measurement of Potential Output"
- R. J. Larner, "Ownership and Control in the 200 Largest Nonfinancial Corporations, 1929 and 1963"
- M. F. Long, "Foreign Graduate Students in Economics"
- M. C. Lovell and William Brainard, "Some Simple Propositions Concerning Cost-Push Inflation"
- Thomas Mayer, "The Propensity to Consume Permanent Income"
- Nobuo Minabe, "The Heckscher-Ohlin Theorem, the Leontief Paradox, and a Neoclassical Model of Economic Growth"
- P. A. Neher, "An Implication of the Labor-Surplus Assumption"
- R. R. Nelson, "Full-Employment Policy and Economic Growth"
- Tibor Scitovsky, "A New Approach to International Liquidity"
- Jaroslav Vanek, "A Theory of Growth with Technological Change"
- F. H. Weymar, "The Supply of Storage Revisited"

- O. E. Williamson, "Peak-Load Pricing and Optimal Capacity under Indivisibility Constraints"

Announcements

The *Development Digest*, a quarterly journal prepared for the Agency of International Development by the National Planning Association, is now available to the public. The journal consists primarily of summaries and reprints of and excerpts from articles, books, monographs, and other materials dealing with social and economic development.

Those interested in subscribing should write to Superintendent of Documents, Government Printing Office, Washington, D.C. 20402. U.S. subscription is \$2.50 per year; foreign subscription, \$3.00 per year; and single copies are available at \$.65 each.

Commencing with this issue of the *AER*, the *Periodicals* listings will appear in *The Journal of Economic Abstracts*. This *Journal* will be distributed to all members of the American Economic Association.

Deaths

Thomas C. Adams, November 7, 1965.

William H. Brown, Jr., associate professor of economics, Swarthmore College, January 16, 1966.

Stephen Cook, Detroit, Michigan.

John L. Dillinger, January 14, 1966.

H. LaRue Frain, emeritus professor of economics, Wharton School, University of Pennsylvania, October 4, 1965.

Harry G. Friedman, New York, November 21, 1965.

Branko Majstorovich, government statistician and economist, Illinois Bureau of Employment Security, March 9, 1966.

Constatine E. McGuire, Washington, D.C., October 22, 1965.

Herbert von Beckerath, emeritus professor, Duke University, in Washington, D.C., March 11, 1966.

Albert Conser Whitaker, professor emeritus of economics, Stanford University, October 14, 1965.

Retirements

James W. Angell, professor of economics, Columbia University, June 1966.

Ralph Conwell, professor emeritus, University of Wyoming, July 1966.

Walter L. Foster, assistant professor, department of economics, The City University of New York, August 1966.

W. A. Guinn, professor of insurance, College of Business Administration, University of Arkansas.

Louis M. Hacker, professor of economics, Columbia University, terminal leave, June 1966.

William M. Hench, professor of economics, The Pennsylvania State University.

Eastin Nelson, professor, department of economics, University of Texas, January, 1966.

Visiting Foreign Scholars

Jagdish Bhagwati, Delhi School of Economics, Delhi University: visiting professor of economics, Columbia University, 1966-67.

Kurt Martin, University of Manchester: visiting professor of economics, Princeton University, academic year 1966-67.

Promotions

- Gerald O. Bierwag: associate professor of economics, University of Oregon.
- David Burger: associate professor, department of political science and economics, State University College, Oswego, New York.
- John F. Chant: associate professor of economics, Queen's University, Ontario, September 1966.
- Edward L. Claiborn: associate professor of economics, U.S. Air Force Academy.
- Paul A. David: associate professor of economics, Stanford University, fall 1966.
- Donald J. Dewey: professor of economics, Columbia University.
- Alexander Erlich: professor of economics, Columbia University.
- Irwin Feller: assistant professor of economics, The Pennsylvania State University.
- Virginia Galbraith: professor of economics, Mount Holyoke College, July 1966.
- Francis W. Gathof: associate professor of economics and business, Beloit College.
- Bruce Glassburner: professor, department of economics, University of California, Davis, July 1966.
- Myron A. Grove: associate professor of economics, University of Oregon.
- Raymond W. Hooker: associate professor of economics, University of Wyoming.
- John J. Klein: professor, department of economics, Fordham University.
- Howard D. Marshall: professor of economics, Vassar College, July 1966.
- Thomas R. Masterson: professor of business administration, School of Business Administration, Emory University.
- Ronald I. McKinnon: associate professor of economics, Stanford University, fall 1966.
- Constantine Michalopoulos: assistant professor of economics, Trinity College.
- Sarah S. Montgomery: associate professor of economics, Mount Holyoke College, July 1966.
- Harold J. Noah: associate professor of economics of education, Teachers College, Columbia University.
- Edward B. Oppermann: associate professor of economics, U.S. Air Force Academy.
- Attiat F. Ott: associate professor, department of economics, Southern Methodist University.
- Robert Piron: assistant professor of economics, Oberlin College.
- Jan S. Prybyla: professor of economics, The Pennsylvania State University.
- Stephen E. Schoderbek: associate professor of economics, U.S. Air Force Academy.
- William O. Shropshire: associate professor, department of economics, Emory University.
- Barry N. Siegel: professor of economics, University of Oregon.
- David C. Smith: professor of economics, Queen's University, Ontario, September 1966.
- Robert G. Taylor: permanent professor, U.S. Air Force Academy.
- Jaroslav Vanek: professor of economics, Cornell University.
- Roger C. Van Tassel: professor, department of economics, Clark University.

Administrative Appointments

- Mario S. Brodersohn: director, Instituto Torcuato Di Tella, Centro de Investigaciones Económicas, Buenos Aires.
- Lester V. Chandler: chairman, department of economics, Princeton University.
- Barend A. de Vries: deputy-director, economics department, World Bank Group, International Bank for Reconstruction and Development.
- Melvin L. Greenhut: professor and head, department of economics, Texas A. and M University.

James H. Hugon: associate director, 1966-67, director, 1967-68, International Business Studies Program, Italian Studies Center, Oregon State System of Higher Education, University of Pavia, Italy.

Andrew M. Kamarck; director, economics department, World Bank Group, International Bank for Reconstruction and Development.

Harold H. Kastner, Jr., Florida State Department of Education: dean, Polk Junior College, Winter Haven, Florida.

Charles A. Lininger: head, Michigan Sample Survey Project for socio-economic data in Peru, with USAID and the Government of Peru, until June 1968.

Thomas D. Mara: director of management programs, Emory University, fall 1965.

Albert G. Matamoros: chief economist, Armstrong Cork Company, Lancaster, Pennsylvania.

Herman L. Myers, Department of State, Mexico: chief, Regional Integration and Trade Division, Department of State, Washington.

Robert Ortner: vice president, Bank of New York.

Leonard S. Silk: vice chairman, Board of Editors, *Business Week*.

William P. Snavely: head, department of economics, University of Connecticut.

Harold K. Strom: director, Transport and Logistics Research Center, University of Oregon, January 1966.

Robert E. Strotz: dean, College of Arts and Sciences, Northwestern University, September 1966.

Guy W. Trump, Emory University: educational director, American Institute of CPAs, New York, September 1965.

Roger C. Van Tassel: acting chairman, department of economics, Clark University.

C. Edward Weber, University of Pittsburgh: professor and dean, School of Business Administration, University of Wisconsin, fall 1966.

Murray L. Weidenbaum: chairman, department of economics, Washington University.

W. Tate Whitman: acting chairman, department of economics, School of Business Administration, Emory University, fall 1965.

Appointments

A. L. Keith Acheson: assistant professor of economics, Queen's University, Ontario, September 1966.

Roger E. Alcaly: instructor in economics, Columbia University, fall 1967.

William M. Bailey: instructor, The American University, Washington.

Leo I. Bakony, Southern Methodist University: Economic Council of Canada, Ottawa, Ontario.

Pranab K. Bardhan: assistant professor of economics, Massachusetts Institute of Technology.

David Barkin: assistant professor of economics and education, Washington University.

Ernest J. Bartell: assistant professor, department of economics, University of Notre Dame.

Ralph Beals: associate professor of economics, Amherst College.

Theodore C. Bergstrom: assistant professor, department of economics, Washington University.

Stanley W. Black, III, Council of Economic Advisers: assistant professor of economics and Bicentennial Preceptor, Princeton University.

Anthony J. Blackburn, Massachusetts Institute of Technology: Mathematica staff.

David F. Bradford: assistant professor of economics, Princeton University.

David A. Bowers, Southern Methodist University: assistant professor, Western Reserve University, September 1965.

William Branson: assistant professor of economics, Princeton University.

Keith Brown, Southern Methodist University: assistant professor of economics and industrial management, Purdue University, September 1966.

Philip Cagan, National Bureau of Economic Research: professor, department of economics, Columbia University, fall 1967.

William F. Campbell, University of Virginia: assistant professor of economics, Louisiana State University, September 1966.

Robert Carlsson, Rutgers University: assistant professor of economics, College of Business Administration, University of South Carolina, September 1966.

James A. Chalmers: assistant professor of economics, Amherst College.

Kang Chao, University of California, Berkeley: assistant professor, department of economics, University of Wisconsin.

Nai-Ruenn Chen, University of California, Berkeley: assistant professor of economics, Cornell University.

Alpha C. Chiang, University of Connecticut: visiting professor of economics, Cornell University.

S. Y. Cho: associate professor of economics, Butler University, September 1966.

Robert M. Coen, Brookings Institution: assistant professor of economics, Stanford University, fall 1965.

John Conlisk, Rice University: assistant professor, department of economics, University of Wisconsin, fall 1966.

William J. Craddock: research associate, department of economics, Iowa State University.

Robert W. Crandall: assistant professor of economics, Massachusetts Institute of Technology.

James R. Crotty, Carnegie Institute of Technology: assistant professor, department of economics, State University of New York, Buffalo.

William I. Davison: associate professor, department of economics, University of Notre Dame.

Floyd R. Dill: assistant professor of economics, Cornell University.

Dennis J. Dugan: assistant professor, department of economics, University of Notre Dame.

A. Thomas Eapen, Federal Reserve Bank of New York: assistant professor of economics, State University of New York, Binghamton and Harpur College.

P. Gail Ellis: assistant professor: The American University, Washington.

Robert Evans: associate professor, department of economics, Brandeis University.

Heywood Fleisig, Yale University: assistant professor of economics, Cornell University.

Duncan K. Foley: assistant professor of economics, Massachusetts Institute of Technology.

Hugh W. Folk: associate professor, department of economics, and associate professor, Institute of Labor and Industrial Relations, University of Illinois, fall 1966.

James A. Gentry, Jr.: assistant professor of business administration, School of Business Administration, Emory University, fall 1965.

Moheb A. Ghali, University of Washington: assistant professor of economics, Rice University, September 1966.

Alan L. Ginsburg: assistant professor, department of economics, The City University of New York.

Howard M. Gitelman, Brandeis University: associate professor, department of economics, College of William and Mary, fall 1966.

Robert Gronau: instructor in economics, Columbia University, fall 1967.

Earl J. Hamilton, University of Chicago: distinguished professor of economic history, department of economics, State University of New York, Binghamton and Harpur College.

Edward H. Hanis: assistant professor of economics, Bowdoin College.

J. William Hanlon: assistant professor of economics, DePauw University.

John R. Harris: assistant professor of economics, Massachusetts Institute of Technology.

Paul T. Hartman: assistant professor, department of economics, University of Illinois, fall 1966.

Paul Hayashi, Southern Methodist University: assistant professor, Arlington State University, September 1965.

John D. Heinberg: assistant professor of economics and public affairs, Princeton University.

A. James Heins: associate professor, department of economics, University of Illinois, fall 1966.

Carl F. Hertz: visiting lecturer, department of economics, Iowa State University, March-May, 1966.

Walter P. Hettich: assistant professor of economics, Queen's University, Ontario, September 1966.

Paul Heyne: associate professor, department of economics, Southern Methodist University, July 1966.

Bert G. Hickman, Brookings Institution: professor of economics, Stanford University, fall 1966.

Toussaint Hočevár, Keuka College: assistant professor of economics, Florida State University.

Dorothy J. Hodges: assistant professor, department of economics, University of Wisconsin.

Richard T. Holmes, University of British Columbia: associate professor, department of economics and commerce, Simon Fraser University, July 1966.

John W. Hooper, Yale University: professor of economics, University of California, San Diego, July 1966.

Melvin E. Horton, University of Washington: instructor in economics, Occidental College.

Joseph C. Horvath, Department of the Interior, Denver: senior economist, Midwest Research Institute, Kansas City, Missouri.

Sheng-tieh Hsiao: visiting assistant professor of economics, University of Colorado, academic year 1966-67.

David S. Huang: associate professor, department of economics, Southern Methodist University, August 1965.

William R. Hughes, Wesleyan University: associate professor of economics, Boston College.

Warren S. Hunsberger: professor of economics, The American University, Washington.

Shane J. Hunt, Yale: associate professor of economics and international affairs and associate director, Graduate Program, Woodrow Wilson School, Princeton University.

Philip Jagolinzer: assistant professor of accounting, University of Maine, Portland.

Estelle D. James, University of California, Berkeley: assistant professor of economics, Stanford University, fall 1965.

David R. Kamerschen, Washington University: associate professor of economics, University of Missouri, September 1966.

K. William Kapp, Brooklyn College, The City University of New York: University of Basel, Switzerland.

David E. Kaun, University of Pittsburgh: associate professor of economics, University of California, Santa Cruz.

Eric Pedersen, University of Stockholm: assistant professor of economics, Florida State University.

Richard L. Peterson, University of Michigan: assistant professor, department of economics, Southern Methodist University, September 1966.

James L. Pierce, Yale University: banking section, Division of Research and Statistics, Board of Governors of the Federal Reserve System.

Michael J. Piore: assistant professor of economics, Massachusetts Institute of Technology.

Jack Ponders: assistant professor, University of Southern California, September 1965.

John P. Powelson: professor of economics, University of Colorado, September 1966.

David Ramsey: assistant professor of economics, University of Missouri, September 1966.

James B. Ramsey, University of Wisconsin: assistant professor of economics, Michigan State University, September 1966.

William S. Rawson, Duke University: assistant professor of economics, College of Business Administration, University of South Carolina, September 1966.

David H. Richardson: assistant professor, department of economics, University of Kansas, fall 1966.

Alejandro Rofman: professor of social accounting, School of Economics, University of the Litoral, Argentina.

Robert Rogow, Michigan State University: assistant professor, department of economics and commerce, Simon Fraser University, summer 1966.

Mark L. Rose: Mathematica staff.

James N. Rosse, University of Minnesota: assistant professor of economics, Stanford University, fall 1965.

Beverly K. Schaffer: assistant professor of economics, School of Business Administration, Emory University, fall 1966.

Lawrence H. Seltzer: visiting distinguished professor of economics, Swarthmore College, first semester, 1966-67.

Stephen L. Shapiro: instructor, department of economics, Old Dominion College, fall 1966.

Mordechai Shechter: research associate, department of economics, Iowa State University.

Miguel Sidranski: assistant professor of economics, Massachusetts Institute of Technology.

Som Liem: assistant professor of economics, Amherst College.

William F. Staats, Rice University: Federal Reserve Bank of Philadelphia.

Richard E. Stanley, Jacksonville University: associate professor of marketing, College of Business Administration, University of South Carolina, July 1966.

James L. Stern: professor, department of economics, University of Wisconsin.

Joseph E. Stiglitz: assistant professor of economics, Massachusetts Institute of Technology.

Koji Taira, International Labor Organization, Geneva: associate professor of economics, Stanford University, winter 1965-66.

Samuel H. Talley: assistant professor of business and economics, University of Maine.

Morris Teubal: assistant professor of economics, University of Minnesota, September 1966.

Adrian W. Throop: assistant professor of economics, Amherst College.

Harry M. Trebing: professor of economics and director, Institute of Public Utilities, Michigan State University, July 1966.

George M. von Furstenberg, Brookings Institution: assistant professor of economics, Cornell University.

Roger W. Walker: visiting lecturer, department of economics, Iowa State University, March-May, 1966.

A. Peter Walshe: assistant professor, department of economics, University of Notre Dame.

Stanley L. Warner, Jr.: assistant professor of economics, University of California, Santa Cruz.

R. L. Weissman: visiting professor of economics, Niagara University, New York.

Finis Welch, University of Chicago: associate professor, department of economics, Southern Methodist University, September 1966.

Terry Wilford: A.I.D. program economist, Latin America, November 1965.

James Willis: assistant professor, Arlington State University, September 1965.

Alan R. Winger: assistant professor, department of economics, College of Business and Economics, University of Kentucky.

Melvyn L. Woodward, Kent State University: associate professor of management, College of Business Administration, University of South Carolina, September 1966.

Patrick Yeung: instructor, department of economics, University of Illinois, fall 1966.

Arnold Zellner, University of Wisconsin: professor, department of economics, University of Chicago.

Robert Zevin, University of California, Berkeley: instructor in economics, Columbia University, fall 1967.

Leaves for Special Appointments

Patrick M. Boarman, Bucknell University: visiting professor, Graduate Institute of International Studies, Geneva, Switzerland, 1965-66.

Alfred Carlip, State University of New York, Binghamton and Harpur College: Fulbright lecturer, National Taiwan University, 1966-67.

Carl F. Christ, Johns Hopkins University: Keynes visiting professor of economics, University of Essex, 1966-67.

Arthur T. Dietz, Emory University: Institut pour l'étude des Methodes de Direction de l'entreprise (IMEDE), University of Lausanne, Switzerland, academic year 1965-66.

Douglas F. Dowd, Cornell University: Fulbright professor of economics, Johns Hopkins University Center for International Studies, Bologna, Italy.

Edgar O. Edwards, Rice University: program specialist, Ford Foundation, Ministry of Economic Planning and Development, Government of Kenya, academic years 1966-68.

John Hein, Federal Reserve Bank of New York: staff, Economic Research Institute, Dublin, Ireland, May-October 1966.

Harley Hinrichs, University of Maryland: visiting assistant professor, department of economics, University of Wisconsin, first semester 1966-67.

Joseph S. La Cascia, University of Omaha: visiting Fulbright lecturer, University of the Northeast, Argentina, July-November, 1966.

John La Tourette, State University of New York, Binghamton and Harpur College: Brookings Research Professorship, 1966-67.

Darrell R. Lewis, Luther College: visiting assistant professor of economics, Louisiana State University, academic year 1966-67.

Ta-Chung Liu, Cornell University: Ziskind visiting professor of economics, Brandeis University.

Michael McCarthy, Brookings Institution: visiting associate professor, department of economics, Southern Methodist University, spring 1966.

Howard W. Nicholson, Clark University: program director for economics, National Science Foundation, Washington.

Eli Schwartz, Lehigh University: visiting lecturer, London School of Economics, fall term, 1966.

William O. Thweatt, Vanderbilt University: visiting professor of economics, Institute of Economic Research, São Paulo University, Brazil, February 1966-August 1967.

HAROLD HOTELLING

DISTINGUISHED FELLOW

1965

To have pioneered in the development of American mathematical statistics would be fame enough for any scholar. But to have pioneered as well in applying mathematical tools to the study of economics makes Harold Hotelling indeed a prophet with honor in his own country. The welfare economics of marginal cost pricing and taxation, the properties of demand and supply functions, and the behavior of prices over space and time—all have yielded to the prepared genius of this inspired teacher.

FOREIGN ASSISTANCE AND ECONOMIC DEVELOPMENT

By HOLLIS B. CHENERY AND ALAN M. STROUT*

Most underdeveloped countries depend heavily on external resources to increase their per capita income. A crude measure of this dependence is the net flow of some \$9 billion per year from advanced to less developed countries, which is equal to a quarter of their gross investment and nearly a third of their imports.¹ Equally important is the provision of skilled manpower and transfer of technical skills through foreign assistance.

The institutional framework for this resource transfer has changed profoundly over the past ten years. Programs of foreign assistance have replaced colonial relations, and donors and recipients now agree that economic and social development is their primary objective. Private investment, which now comprises only a quarter of the total resource flow, is increasingly screened for its contribution to the recipient country's development. Thus the inflow of external resources—which can loosely be called “foreign assistance”²—has become virtually a separate factor of production, whose productivity and allocation provide one of the central problems for a modern theory of development.

The possibilities of securing rapid and sustained development by effective use of foreign assistance have been strikingly demonstrated in the past decade by such countries as Greece, Israel, Taiwan, and the Philippines. In each case, a substantial increase in investment financed

* The research on which this article is based was carried out by the Office of Program Coordination of the U.S. Agency for International Development. The analysis and judgments expressed are the sole responsibility of the authors. The authors are, respectively, professor of economics at Harvard University, and acting chief, Policy Planning Division, AID. They are indebted to Jaroslav Vanek, Joel Bergsman, Lorene Yap, Paula Tosini, and Carmel Ullman of AID in carrying out the analysis, and to Irma Adelman, Samuel Bowles, Francis Bator, David Cole, Robert Dorfman, and Stephen Lewis for helpful comments. An early version of the paper was presented by Chenery to the Boston meeting of the Econometric Society in December 1963. A more complete statistical analysis is given in [8].

¹ The OECD countries' component of this flow in 1963 and 1964 averages \$8.3 billion, of which 70 per cent was from public sources [16].

² The Development Assistance Committee of the OECD defines “assistance” to include public grants and loans of more than five years' duration; it also uses a broader definition which includes private investment. The latter is more convenient for our purposes, although obviously only part of the total is “assistance” in the sense of an unrequited transfer of resources. The significance of the term as used here is that it represents a governmental decision by lenders and borrowers to secure a given transfer of resources.

largely by foreign loans and grants has led to rapid growth of GNP followed by a steady decline in the dependence on external financing. Not only was growth accelerated by foreign assistance, but the ability of each economy to sustain further development from its own resources was very substantially increased.³

The present study first outlines a theoretical framework designed to analyze the process of development with external assistance in quantitative terms. This framework is then used to evaluate the current performance of the developing countries and to assess their future needs for assistance under various assumptions. The evaluation suggests a range of practical possibilities for accelerating growth through external aid as well as some of the conditions which may frustrate this objective. The comparative analysis also suggests some international standards of performance which might facilitate the planning and execution of programs of foreign assistance.

I. Aid and the Transition to Sustained Growth

Modern theories of economic development⁴ investigate the process by which a poor, stagnant economy can be transformed into one whose normal condition is sustained growth. There is general agreement on the principal changes that characterize this transformation: an increase in human skills, a rise in the level of investment and saving, the adoption of more productive technology, a substantial change in the composition of output and employment, the development of new institutions, etc. There has been relatively little analysis, however, of the possibility of accelerating these changes through the use of significant amounts of external resources over a limited period of time.

A country setting out to transform its economy without external assistance must provide for all of the requirements of accelerated growth from its own resources or from imports paid by exports. Success thus requires a simultaneous increase in skills, domestic saving, and export earnings as well as an allocation of these increased resources in such a way as to satisfy the changing demands resulting from rising levels of income. The attempt to increase output can be frustrated by failure in any one of these attempts, even when the others have been quite successful. When growth is limited in this way by a few bottlenecks, there is likely to be underutilization of other factors such as labor, natural resources, and specific types of productive capacity.

By relieving these constraints, foreign assistance can make possible fuller use of domestic resources and hence accelerate growth. Some of the

³ This conclusion is documented in more detailed studies of Israel [6], Greece [1], and Taiwan [12].

⁴ For example, Lewis [13], Rostow [20], Gerschenkron [10], and Ranis and Fei [17].

potential bottlenecks—of skills, savings, or foreign exchange—can be temporarily relaxed by adding external resources for which current payment is not required. More efficient use can then be made of other resources, so that the growth of total output may be substantially higher than would be permitted by the rate of increase of the most restrictive domestic factor.

While this alternative sequence recognizes the existence of a given set of requisites for continued growth, it makes the timing of their appearance much more flexible. The full set of requirements need only become available from domestic sources as the inflow of foreign resources is reduced. To achieve this result, the additional resources produced through more rapid growth must be used to make good the deficiencies which are temporarily being supplied from outside assistance.⁵

Two basic questions may be raised as to the feasibility of such a sequence. The first is the extent to which foreign resources can actually substitute for missing local factors and permit an increase in total output. The second is whether countries which have achieved some initial success through external assistance will take the further steps needed to reduce their dependence on it in the future. These issues will be discussed in Section II.

A. External Resources and the Limits to Growth

The impact of external resources on the growth of an economy can be judged by their contribution to the mobilization and allocation of all productive resources. Three types of resources should be distinguished: (1) the supply of skills and organizational ability; (2) the supply of domestic saving; and (3) the supply of imported commodities and services. At any moment in time these factor supplies represent separate limits to economic growth. While investment can be devoted to increasing the supplies of skills or of imported commodities (through import substitution or raising exports), changes in these factor supplies can only be brought about gradually. They are also substitutes in the production process to only a limited degree in the short run.

Aggregate growth models usually focus on the saving limit, which in a closed economy also sets the investment limit. When external financing is available, however, we need to examine other limits to the ability to increase investment. These may result either from limited supplies of skilled labor, entrepreneurs and other inputs complementary to the investment process or from the limited market expected for the output. The evidence cited below shows that underdeveloped countries have

⁵ In criticizing the notion of a fixed set of "prerequisites" to industrialization, Gerschenkron [10] suggests other possibilities of substitution for the missing requirements which stimulate their subsequent development.

demonstrated an ability to raise the level of investment much more rapidly than the level of saving. Sustained rates of increase in investment of 12–15 per cent per year are common, while typical figures for saving growth are 6–8 per cent.⁶

A third factor which may limit the possibilities for accelerated growth is a country's inability to change its productive structure to meet the changing patterns of internal and external demand. Although this problem is not likely to be serious in a slowly developing economy, rapid growth requires a large increase in the supplies of machinery and equipment, raw materials, and other manufactured goods that are typically imported in a poor country. The more rapid the rate of growth, the larger the reallocation of labor and capital away from traditional patterns that will be needed to prevent bottlenecks developing. If this reallocation is not sufficiently rapid, shortages of imported goods will provide a limit to further growth quite apart from the investment limitation. This import limit reflects the inability of the economy to provide the composition of output—from domestic sources plus imports—that is required by its level of income, rate of investment, and pattern of consumer demand. In cases of acute shortages of imported goods, the economy will be unable to transform potential saving into investment because of insufficient supplies of investment goods.

The foregoing description of underdeveloped countries as characterized by persistent resource bottlenecks may be summed up as a hypothesis of limited structural flexibility. In the short run—for periods of five to ten years—we will describe such an economy by a set of linear relationships in the Harrod-Domar tradition which determine the pattern of growth under given assumptions as to government policy. This basic model will be used to evaluate current performance as well as to make 5–10-year projections. For longer periods, we will use a model based on the neoclassical view that domestic resources can be substituted for imports to the extent required by changing demands, although with diminishing productivity. This second model has the effect of reducing the aid requirements for any given pattern of growth. Since most underdeveloped countries fall somewhere between the two extreme cases, the use of both models for projections indicates the probable limits to the range of aid requirements.

1. *The Basic Model.*⁷ To simplify our analysis, we shall develop a basic model of the role of aid in the transition in two steps. We consider

⁶ These and other characteristics of a sample of 31 underdeveloped countries are summarized in Table 1.

⁷ This model is taken from Chenery and Bruno [6], which utilizes a detailed analysis of the economic structure of Israel. The derivation of the three aggregate limits from an interindustry programming model is given there.

first the case in which only the first two resource limits—on skills and saving—are relevant; this situation will be described as *investment limited growth*. It includes the Harrod-Domar model as the limiting case of no external assistance. We then take up the possibilities for achieving self-sustaining growth when the balance of payments limit is effective. This situation will be identified as *trade limited growth*. The complete model includes all three potential limits.

The principal endogenous variables and parameters to be used in the basic model are the following:

Endogenous Variables (subscript indicates year)

- V_t Gross National Product
- I_t Gross investment
- S_t Gross domestic savings
- \bar{S}_t Potential gross domestic savings
- M_t Imports of goods and services
- \bar{M}_t Required imports of goods and services
- E_t Exports of goods and services
- F_t Net inflow of foreign capital
- C_t Consumption

Parameters

- \bar{r} Target rate of growth of GNP
- r_t Rate of growth of GNP in year t
- α' Marginal savings rate ($\Delta \bar{S} / \Delta V$)
- α_t Average savings rate in year t (S_t / V_t)
- β Maximum rate of growth of investment
- k Incremental gross capital-output ratio ($I / \Delta V$)
- μ' Marginal import rate ($\Delta \bar{M} / \Delta V$)
- μ_t Average import rate in year t (M_t / V_t)
- Φ_t Ratio of foreign capital inflow to GNP in year t (F_t / V_t)
- ϵ Rate of growth of exports

Since the basic model is designed to explain the functions of aid and to evaluate current performance of developing countries, it is useful to have in mind the typical values of the principal parameters. Table 1 gives the upper quartile, median, and lower quartile values of each parameter for a sample of 31 countries during the period 1957–62. The sample covers most of the underdeveloped world, and the median values are quite close to the aggregate U.N. estimates for all underdeveloped countries.⁸ The median capital-output ratio (3.5) and saving rate (.12)

⁸ The U.N. estimates investment at 16 per cent of GNP in 1960 and a growth of GNP of 4.4 per cent for the previous decade [23, pp. 19, 37].

TABLE 1—DISTRIBUTION OF PARAMETER VALUES, 31-COUNTRY SAMPLE

Parameter	Symbol	Upper Quartile	Median	Lower Quartile
Highest 5 years in recent past	β	.19	.14	.10
Compound growth rate of gross investment				
Relationships during 1957-62				
Compound growth rate of gross investment	i	.12	.07	.01
Incremental capital-output ratio (assuming 1-year lag)	k	2.78	3.52	4.72
Compound growth rate of GNP	r	.062	.046	.034
